É AUTORIZADA A REPRODUÇÃO INTEGRAL DESTA TESE/TRABALHO APENAS PARA EFEITOS DE INVESTIGAÇÃO, MEDIANTE DECLARAÇÃO ESCRITA DO INTERESSADO, QUE A TAL SE COMPROMETE

Universidade do Minho, 20 de Fevereiro de 2012

Assinatura: \_\_\_\_\_

The work presented in this thesis was mainly done within the Microbiology and Infection Research Domain in the Life and Health Sciences Research Institute (ICVS), School of Health Sciences, University of Minho. Part of the work was also done in the Apoptosis Research Centre of the Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada and in the Department of Biology and CESAM, University of Aveiro, Portugal. The financial support was given by Fundação para a Ciência e Tecnologia by means of a project PTDC/BIA-MIC/114116/2009 and also by a grant, SFRH/BD/33125/2007.

## AGRADECIMENTOS

No fim do percurso há que olhar para trás e agradecer a todos aqueles que, à sua maneira, nos guiaram e acompanharam na viagem.

Começo por agradecer à Professora Doutora Paula Ludovico pela excelente orientação ao longo destes anos, pelo constante apoio e incentivo, preciosos conselhos, críticas e sugestões e principalmente pelo rigor demonstrado... Obrigada por se mostrar sempre disponível para me ajudar a atingir os meus objetivos. Obrigada Paula! Foi uma viagem muito enriquecedora, pessoal e profissionalmente...

À Doutora Elsa Logarinho, gostaria de expressar o meu reconhecimento por todo o auxílio durante estes anos, e pela útil partilha do seu conhecimento.

Ao Professor Fernando Rodrigues, pelo apoio e pelas longas discussões científicas que tanto me ajudaram durante todos estes anos.

Ao ICVS, na pessoa da Professora Cecília Leão, queria agradecer a oportunidade e o privilégio de trabalhar neste instituto bem como o incondicional apoio na transposição de todos os obstáculos inerente ao meu trabalho.

I would like to acknowledge Professor Martin Holcik, for his valuable inputs and most of all, for his constant support during my stay in Ottawa, and also to all the people in his group, especially Alura Riley, for helping me with my experiments but more importantly with the cold. It was a real pleasure working with you all!!!

Ao Professor Manuel Santos, pela total disponibilidade demonstrada para me receber no seu laboratório e pelas discussões científicas ao longo destes anos que tanto contribuíram para o sucesso deste trabalho. Laura Carreto, João Paredes, Tatiana Costa, Ana Rita Bezerra, João Simões e Marisa Simões, obrigada por me fazerem sentir em casa e pela ajuda no laboratório...

À Fundação para a Ciência e Tecnologia pelo financiamento que permitiu a realização deste trabalho.

Aos MIRD, antigos ou recentes colegas, por todos os momentos partilhados, pela disponibilidade, ajuda e amizade. Obrigada amigos! No entanto, tenho que destacar duas pessoas a quem tenho que agradecer por terem feito este percurso sempre a meu lado. Foi uma honra Belém e Bruno. Obrigada pelas nossas conversas, científicas ou não. Mais que colegas de bancada foram e serão sempre grandes amigos...

Ao Fernando, a quem, além de agradecer o incondicional apoio, compreensão e companhia nas longas noites e fins-de-semana de clausura no laboratório, tenho que pedir desculpa pelo tempo e espaço que esta viagem nos possa ter roubado. Sem ti este percurso não faria sentido!

Por último, quero agradecer a toda a minha família, principalmente aos meus pais, irmã e cunhado, por todo o apoio e incentivo ao longo não só destes 4 anos mas de toda a minha vida. Peço desculpa por todos os momentos de ausência.... Tudo o que consegui alcançar até hoje foi graças a vocês. Muito obrigada!

## ABSTRACT

Global mRNA translation impairment has been described during the course of apoptosis in both mammalian and yeast. Nevertheless, the molecular pathways modulating translation during different scenarios of yeast apoptosis are still largely unexplored. Here we show by polysome profile analysis an impairment in cap-dependent translation initiation, correlated with alterations in translation machinery, such as the decrease in eIF4A levels and the phosphorylation of eIF2 $\alpha$  by Gcn2 protein kinase upon acetic acid treatment. Gcn2p proved to play a preponderant role for the progression of the acetic acid-induced apoptosis, not only through the repression of cap-dependent translation initiation, but also by the induction of a cell cycle arrest in G0/G1 phase. Despite the observed impairment of cap-dependent translation initiation, some mRNAs, such as *AIF1* and eIF4G, were translated during acetic acid treatment. eIF4G harbors an IRES in the 5' untranslated region (5'UTR) of the mRNA allowing its translation by a cap-independent IRES-mediated translation, being also crucial for an efficient IRES-mediated translation of other mRNAs. The inhibition of the cap-dependent translation initiation associated with the observation of *AIF1* and eIF4G efficient translation during acetic acid treatment made us question the possibility of an alternative IRES-mediated translation occur during acetic acid treatment.

Furthermore, the translation machinery alterations proved to be dependent of the yeast caspase like protease, metacaspase, which induced also the specific fragmentation of the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH). Although metacaspase role in the induction of the apoptosis is well established, its specific substrates were still unknown. The fact that GAPDH is specifically cleaved by metacaspase, suggests a role of this enzyme in the apoptotic process. In mammalian cells, GAPDH interacts with some virus and cellular mRNAs repressing their internal ribosome entry site (IRES)-mediated translation. GAPDH cleavage by caspase-1 during apoptosis suggests a regulation of its function by derepression of the IRES-mediated translation.

Upon the inhibition of translation initiation during acetic acid treatment, eEF1A, a translation elongation factor responsible for the delivery of aminoacyl-tRNAs to the ribosomes, appears to play a function unrelated to translation

elongation. A proteomic analysis combined with a proteinase K assay showed that upon acetic acid treatment, eEF1A is fragmented and the eEF1A N-terminal fragments are present in mitochondria where they appear to play a pro-apoptotic role. Apart from its role in translation this protein is also an actin-binding protein being responsible for the actin cytoskeleton organization. This re-localization to mitochondria reduces its binding to actin leading to actin cytoskeleton alterations which proved to be conserved from yeast to mammalian cells.

Our previously reported proteomic analysis in the same apoptotic conditions revealed an increased expression of heat shock protein 90 (HSP90) isoforms. We herein demonstrate by microarray analysis of polysomal mRNAs combined with the HSP90 isoforms 5' untranslated region (5'UTR) expression in monocistronic reporter plasmids harboring an hairpin, that HSP90 isoforms are translated by a cap-independent mechanism mediated by (IRES) elements. Moreover, genetic abrogation of HSP90 isoforms indicate divergent roles for HSP90 isoforms, Hsc82 acts as a pro-survival and Hsp82 as a pro-death molecule, upon the acetic acid treatment. In fact, the deletion of *HSC82* leads to a severe necrotic cell death, in spite of an apoptotic cell death, upon acetic acid treatment. These undisclosed functions of yeast HSP90 isoforms were confirmed through pharmacological inhibition of HSP90 activity, using 17-allylaminogeldanamycin (17AGG), and by the overexpression of each HSP90 isoform during acetic acid. These results suggest that the efficiency of HSP90 isoforms mRNA translation is an important component of the cellular response to acetic acid. In summary, the results presented in the scope of this thesis contributed to the understanding of the translation mechanisms regulating yeast cell death processes.

## RESUMO

A inibição global da tradução foi descrita no decurso da apoptose tanto em leveduras como em mamíferos. No entanto, as vias moleculares que modulam a tradução em diferentes cenários de morte celular programada (MCP) em levedura são ainda desconhecidas. Neste trabalho demonstramos, através de perfis polissomais, uma inibição da iniciação da tradução dependente da estrutura cap, correlacionada com alterações na maquinaria de tradução, tais como a redução dos níveis de eIF4A e a fosforilação do eIF2 $\alpha$  mediada pela cinase Gcn2p, durante o tratamento com ácido acético. Gcn2p provou desempenhar um papel relevante na progressão da morte induzida por ácido acético não só pela repressão da iniciação da tradução dependente de cap mas também através da indução de um bloqueio do ciclo celular na fase G0/G1. Apesar da diminuição da iniciação da tradução dependente de cap, alguns mRNAs, tais como o *AIF1* e o eIF4G, são traduzidos durante o tratamento com ácido acético. eIF4G possui um *internal ribosome entry site* (IRES) na região 5' não traduzida (5'UTR) do mRNA o que permite a sua tradução independente de cap, sendo também fundamental para a tradução eficiente de outros mRNAs regulados por IRES. A inibição da iniciação da tradução dependente de cap associada à observação da tradução de *AIF1* e eIF4G levanta a possibilidade da ocorrência de uma tradução alternativa mediada por IRES durante o tratamento com ácido acético. Para além disso, as alterações na maquinaria de tradução observadas durante o tratamento com ácido acético parecem ser dependentes da ação da caspase de leveduras, a metacaspase, que provou ser ainda responsável pela clivagem específica da enzima glicolítica gliceraldeído-3-fosfato desidrogenase (GAPDH). Embora a importância da metacaspase na execução da apoptose esteja bem estabelecida, os substratos desta protease são ainda desconhecidos. O fato da GAPDH ser especificamente clivada pela metacaspase, sugere um papel desta enzima no processo apoptótico. Em mamíferos, a GAPDH interage com alguns mRNAs celulares e de vírus inibindo a sua tradução mediada por IRES. A clivagem da GAPDH pela caspase-1 durante a apoptose sugere uma regulação da sua função na tradução e a desrepressão da tradução mediada por IRES. Após a inibição da iniciação da tradução durante o

tratamento com ácido acético, o fator de elongação da tradução eEF1A, responsável pela entrega dos aminoacil-tRNAs nos ribossomos, parece desempenhar uma função independente do processo de tradução. Uma análise proteômica em conjunto com um ensaio de proteinase K mostraram que, após o tratamento das células com ácido acético, o eEF1A é fragmentado e os fragmentos N-terminais de eEF1A são detetados na matriz mitocondrial onde parecem desempenhar um papel pró-apoptótico. Para além da sua participação no processo de tradução esta proteína está também associada à actina sendo responsável pela organização do citoesqueleto de actina. A realocização para a mitocôndria reduz a sua ligação à actina induzindo alterações no citoesqueleto de actina que provaram ser conservados tanto em levedura como em mamíferos.

Anteriormente, uma análise proteômica, nas mesmas condições apoptóticas, revelou um aumento dos níveis das isoformas da proteína de choque térmico 90 (HSP90). A análise de microarrays dos mRNAs presentes em frações polissomais complementada com a expressão dos 5'UTR das isoformas da HSP90 em plasmídeos monocistrônicos contendo um gancho no 5'UTR, demonstrou a presença de IRES no 5'UTR das HSP90 mediando a sua tradução independente de cap. A deleção genética das isoformas das Hsp90 sugere que estas desempenham funções divergentes durante o tratamento com ácido acético, Hsc82p atua como uma molécula de sobrevivência e Hsp82p como uma molécula pró-apoptótica. Além disso, a deleção da *HSC82* conduz a uma drástica morte celular necrótica durante o tratamento com ácido acético, sugerindo que estas isoformas são cruciais para o balanço e equilíbrio entre a apoptose e a necrose. Estas novas funções das isoformas da HSP90 foram confirmadas através da inibição farmacológica da atividade das HSP90, utilizando 17-allylaminogeldanamycin (17AGG), e da sobreexpressão de cada isoforma em células tratadas com ácido acético. Estes resultados sugerem que a eficiência de tradução do mRNA das isoformas da HSP90 é um componente importante da resposta celular ao ácido acético. Em resumo, os resultados apresentados no âmbito desta tese contribuíram para o aumento do conhecimento dos mecanismos de tradução que regulam o processo apoptótico em levedura.

## OBJECTIVES AND OUTLINE OF THE THESIS

In mammalian cells, posttranslational modifications and cleavage of translation factors by caspases during programmed cell death (PCD) lead to the impairment of cap-dependent translation. Nevertheless, a selective internal ribosome entry site (IRES) mediated translation is activated regulating the expression of PCD regulators, both anti- and pro-apoptotic proteins.

In yeast, a conservation of the alternative translation mechanisms regulating PCD is far from being completely disclosed. Despite the report that the fragmentation of translation factors occurs in different scenarios of yeast PCD, the role of yeast metacaspase in alterations and the evaluation of alternative translation mechanisms controlling yeast PCD have never been addressed.

The work reported in this thesis aimed to get new insights on the yeast translation regulatory mechanisms activated during PCD and on the proteins translated by these mechanisms as well as their contribution for the PCD process.

With the intention to drive the reader through the main achievements, this thesis was organized in five chapters:

In **chapter 1**, a general introduction mainly centered on the knowledge of the PCD processes and the translation regulatory mechanisms of PCD will be given.

In **chapter 2**, a characterization of the translation process and translation regulators modulating acetic acid-induced PCD, will be done.

In **chapter 3**, insights on the conservation of molecular pathways targeted by proteases during yeast apoptosis will be exposed. Furthermore, results are presented suggesting a new pro-apoptotic function of translation elongation factor 1A (eEF1A) upon acetic acid-induced apoptosis.

In **chapter 4**, results will be presented indicating that heat shock protein 90 (HSP90) chaperones isoforms are translated by an IRES-mediated cap-independent mechanism during acetic acid treatment, playing antagonistic roles in yeast PCD.

Finally, **chapter 5** comprises an integrative discussion focused on the main contributions of the present work to the understanding of the yeast PCD processes, combined with future perspectives.

## CHAPTER 1

---

### **General introduction**

## 1.1 PROGRAMMED CELL DEATH (PCD)

The crucial role of cell death in the cellular homeostasis has been widely described [6-8], however, it was only recognized after the discovery that cell death in multicellular organisms is subjected to genetic control, and the demonstration that abnormalities in cell death regulation lead to the onset of several diseases, including neurodegenerative diseases and several forms of cancer [6, 9-12]. The first description of the programmed cell death (PCD) process and its role in cellular homeostasis was in the 1960s when an insect physiologist, Carrol M. Williams, and his group referred for the first time to PCD, meaning that cells followed a sequence of controlled (and thereby implicitly genetic) steps towards their own destruction [13]. In 1972, John Kerr and coworkers generalized the idea that cell death followed a specific pattern that included shrinkage of the cell, apparently little damage to the organelles, coalescence and margination of chromatin and fragmentation of the cell and the nucleus [14]. These observations suggested that the ritualistic nature of cell death implied an organized and conserved mechanism: cell death was an aspect of life like any other [14]. Further reports followed, describing two distinct types of PCD, apoptosis and necrosis, based on morphological and biochemical criteria [12, 13, 15-19]. Apoptosis is the best studied and described type of PCD. The term apoptosis emerged in the early 1970 [14], although the phenomenon of apoptosis had been described already in the late 1700s. The word, apoptosis, is derived from Greek roots meaning, "dropping off" e.g. falling of leaves. The genetics and molecular mechanisms of apoptosis were first characterized in the late 1980s and early 1990s in studies using the nematode worm *Caenorhabditis elegans*. Apoptosis during *C. elegans* development is extremely precise and predictable specific genes are activated to kill exactly 131 cells, leaving 959 in the adult worm [20-22]. In other words, apoptosis is an evolutionarily conserved, genetically regulated, cellular suicide mechanism that plays a crucial role in development and in the defence of homeostasis.

For many years necrosis was considered as an alternative to apoptotic programmed cell death [18, 23]. However, in the last decade, necrosis has becoming accepted as a form of active and controlled PCD [18, 23-28] that under pathophysiological conditions, amplifies and catalyzes the pathological process therefore activating an

inflammatory response [18, 23]. The morphology of necrotic cells is very distinct from that of cells undergoing apoptosis. Structural changes occur both at the cytoplasm and the nucleus [18, 19, 23-31], chromatin flocculates and plasma membrane integrity is compromised releasing the cytoplasmic contents into the extracellular space leading to inflammation [18]. Unlike in apoptosis, the chromatin is not packed into discrete membrane-bound particles, but it forms many unevenly textured and irregularly shaped clumps, a feature that is being used for differentiating between the two modes of cell death. The mitochondria undergo inner membrane swelling and disintegration. Polyribosomes are dissociated and dispersed throughout the cytoplasm, giving the cytoplasmic matrix a dense and granular appearance and swelling and fragmentation of the cisterns of rough endoplasmic reticulum and Golgi apparatus are frequently observed. Necrotic cell death can be mediated by passive as well as active mechanisms. However, the molecules involved in the active mechanisms are just starting to be identified [18, 23-28]. The involvement of the death domain receptors like tumour necrosis factor (TNF) receptor 1 (TNFR1), Fas/CD95 and TRAIL-R or toll like receptors (TLR) 3 and 4 in the activation of necrosis by a mechanism dependent on the kinase RIP1 has been described [25, 32-34].

During the apoptotic PCD, characteristic morphological alterations are also observed, such as cytoplasmic shrinkage, nuclear condensation and cytoplasmic blebbing. These initial changes are followed by fragmentation of the nuclear contents and subsequent encapsulation of these fragments into apoptotic bodies [12, 14, 15, 19, 30], which are quickly phagocytised and digested by neighbouring cells or macrophages [12, 14, 35, 36]. As no cytosolic contents are released into the intercellular medium during apoptosis, inflammation is not triggered [39].

Biochemically, apoptotic cells are characterized by the production of reactive oxygen species (ROS), reduction in the mitochondrial transmembrane potential, intracellular acidification, externalization of phosphatidylserine for the cytoplasmic outer membrane, selective proteolysis of a subset of cellular proteins, and degradation of DNA into internucleosomal fragments [9, 12, 15, 37]. These

characteristic manifestations of apoptosis reflect the activation of an intrinsic cell death apparatus well conserved in eukaryotes [3, 12, 20-22, 26, 36, 38-41].

**Figure 1** – Mammalian caspase family and *C. elegans* caspase CED-3. The structural and functional organization of caspases. From [1].

During apoptosis, a proteolytic system involving a family of proteases called caspases is activated [42-45]. Caspases are aspartate-specific cysteine proteases responsible for the cleavage of key enzymatic and structural substrates, resulting in the systematic and orderly disassembly of the dying cell [42-48]. These proteases were first implicated in apoptosis by genetic analysis in the nematode *C. elegans*, in which the deletion of a single gene, CED-3, resulted in the abrogation of PCD in the 131 cells normally undergoing apoptosis during the worm's development [21]. The mammalian caspase family of proteases consist of at least 14 mammalian members that can be divided, according to their structure and function, into initiator (pro-caspases 2, 8, 9 and 10) and effector (pro-caspases 3, 6 and 7) caspases (Figure 1). These proteases are constitutively expressed in almost all cell types as inactive proenzymes (zymogens) that become processed and activated in

response to a variety of pro-apoptotic stimuli [44]. Caspase activation involves proteolytic processing of the proenzyme at specific aspartate residues between the domains, resulting in removal of the prodomain as well as the linker region and formation of a heterodimer containing one large and one small subunit. The active caspase is a tetramer composed of two such heterodimers [44]. Initiator caspases are responsible for the activation of the effector pro-caspases which after activation carry on an apoptotic cascade culminating in the cellular disassembling. This cascade begins with autocatalytic activation of initiator caspase (caspase-2, -8, -9 and -10) that, in turn, transmit the signal by cleaving and thereby activating the

**Figure 2** – Death receptor-signalling pathway and mitochondrial pathway of apoptosis. From Cell Signalling ([http://www.cellsignal.com/reference/pathway/Death\\_Receptor.html](http://www.cellsignal.com/reference/pathway/Death_Receptor.html)).

downstream effector/executioners caspases such as caspase-3 [44].

Apoptosis is a highly regulated process, being controlled by tightly interconnected signalling pathways (Figure 2). Some of the pathways and events of the apoptotic program are conserved among species being considered fundamental events in the apoptotic process (Figure 2) [12, 13, 15, 38, 39, 49-51]. These include the action and regulation of the Bcl-2 family of proteins, cytochrome c release from mitochondria into the cytosol accompanied by mitochondrial dysfunction, and activation of caspases (Figure 2). There are two major signalling pathways of apoptosis, the death receptor pathway and the mitochondrial pathway [9, 51-54]. In the death-receptor signaling pathway, signal is provided by the interaction between the ligand and the death receptor. Death receptors, such as Fas/CD95 or TNFR1 belong to the tumor necrosis factor receptor (TNFR) superfamily, and the ligands belong to the tumor necrosis factor (TNF)/nerve growth factor family (Figure 2). Members of the death receptor family contain one to five cysteine-rich repeats in their extracellular domain and a death domain (DD) in their cytoplasmic tail. The DD is essential for initiating the apoptotic signal. Following ligation of death receptor by ligand, the death receptor oligomerizes and recruits adapter molecules and initiator caspases to a complex, the death-inducing signalling complex (DISC), which results in the activation of initiator caspases. Initiator caspases then cleave effector/executioner caspases (caspase-3, -6, and -7), which cleave a number of target substrates resulting in morphologic and biochemical characteristics of apoptosis (Figure 2). Apoptosis is a tightly regulated process. The most extensively studied and perhaps the most relevant regulators are Bcl-2 family proteins. This family includes anti-apoptotic proteins such as Bcl-2 and Bcl-XL, and pro-apoptotic proteins such as Bax and others [9, 55, 56].

These molecules either homodimerize or heterodimerize with molecules of opposing function (e.g. Bax may heterodimerize with Bcl-2 or Bcl-xL). The influence of this interaction in the apoptotic process appears to be dependent on the relative concentration of these molecules in heterodimers and the ratio between pro-apoptotic and antiapoptotic molecules. Though the regulatory role of Bcl-2 family proteins in mitochondrial pathway of apoptosis is well-established [9, 55, 56], their role in the regulation of death receptor signaling is controversial and may

be specific for each cell type. Despite the fact that these two pathways are distinct, death receptor signaling can activate the mitochondrial pathway via tBid [56]. Bid is a BH3-only protein exclusively cytosolic in living cells. Upon activation of cell surface death receptors, Bid is cleaved by active caspase-8 and the truncated Bid (tBid) translocates from cytosol to mitochondria inducing cytochrome c release through the binding to a mitochondria specific lipid, cardiolipin [56]. The ability to cleave and activate Bid may not be limited to caspase-8. Other caspases, such as caspase-3, as well as other proteases, have been shown to cleave and activate Bid. Mitochondria play a crucial role for the progression of the PCD processes [24, 39, 52, 55, 57]. A number of stimuli, including chemotherapeutic agents, UV radiation, stress molecules (ROS and reactive nitrogen species RNS), and growth factor withdrawal appear to mediate PCD via the mitochondrial pathway which can be independent from death-receptor pathway [57, 58].

Mitochondria are organelles comprised by the matrix surrounded by the inner membrane (IM), the intermembrane space and an outer membrane (OM). In the IM are enclosed several molecules, including ATP synthase, electron transport chain, and adenine nucleotide translocator (ANT). Under physiological conditions these molecules allow the respiratory chain to create an electrochemical gradient (membrane potential). The OM contains a voltage-dependent anion channel. The intermembrane space contains holocytochrome c, certain procaspases, adenylate kinase 2, EndoG, Diablo/Smac, and apoptosis-inducing factor (AIF). IM permeabilization leads to changes in mitochondrial membrane potentials while OM permeabilization results in the release of these molecules into the cytoplasm. The release of cytochrome c is one of the major steps in the mitochondrial pathway of apoptosis associated with the permeabilization of mitochondrial OM, promoting the formation of the apoptosome which activates caspase 9 leading to the activation of the executioner caspases to orchestrate apoptosis. The components of apoptosome are cytochrome c, an adapter molecule Apaf-1 (Apoptotic protease-activating factor) and procaspase-9. The binding of cytochrome c to Apaf-1 leads to its unfolding and exposure of its oligomerization domain which is stabilized in the presence of ATP or dATP. Caspase recruiting domain (CARD) in the oligomer binds to the CARD domains of procaspase-9 to activate caspase-9. Active caspase-9

then cleaves and activates executioner caspases, such as caspase-3, to induce apoptosis [57]. CAD (caspase-activated DNase) is responsible for the degradation of chromosomal DNA. Activation of CAD is initiated by the cleavage of ICAD (inhibitor of caspase-activated DNase) by effector caspases, such as caspase-3.

EndoG and AIF are released from mitochondria in response to various stimuli being translocated to the nucleus, where they have a role in DNA degradation. Unlike CAD, activation of EndoG and AIF is independent of caspase activation. It is possible that EndoG and AIF may participate in nuclear DNA degradation when caspase activation is limited by an apoptosis-like mechanism.

PCD is a highly regulated mechanisms under a complex and rigorous molecular control [26]. Although scientists have focused their research in the genetic alterations that regulate PCD, an increasing body of evidence is also emerging showing a tight regulation of the translation process and factors during the PCD process [5, 59, 60].

## 1.2 TRANSLATION CONTROL DURING PCD

Translation process is divided in three phases: initiation, elongation and termination [61]. Canonical cap-dependent translation initiation involves the binding of the mRNA 5'-m<sup>7</sup>G cap-structure to the cap-binding protein eIF4E. eIF4G binds to eIF4E recruiting other proteins such as the eIF4A helicase, responsible for the unfold of the mRNAs 5' untranslated region (5'UTR) secondary structure,

forming the cap-binding complex (eIF4F). After the assembly of the eIF4F complex with the mRNA, 40S ribosomal subunit is recruited originating the 43S complex comprised of the 40S ribosomal subunit, a ternary complex containing an initiator tRNA molecule (tRNA<sup>i</sup>Met), the initiation factor eIF3, which makes the connection between 40S and eIF4G, and the initiation factors eIF1 and eIF1A, which help the recognition of the start codon (Figure 3A). After the assembly, the 43S initiation complex scans along the 5'UTR searching for the initiation AUG codon where the 60S subunit binds to form an elongation-competent 80S ribosome. 5'- and 3'-ends of the mRNA interact during cap-dependent initiation in

**Figure 3** – Cap-dependent and IRES-mediated translation initiation mechanisms. (A) Cap-dependent translation. (B) IRES-mediated translation (i) using most of the canonical translation initiation factors and many ITAFs with the circularization of the mRNA, (ii) using a limited number of canonical factors and ITAFs and (iii) canonical factors are dispensable, but some ITAFs are required. From [5].

eukaryotes through the poly(A)-binding protein (PABP) interaction with eIF4G, leading to the circularization of the mRNA. For decades this cap-dependent initiation of translation was assumed as the only mechanism allowing the progression of cellular mRNAs translation [62, 63].

### 1.2.1 Cap-dependent translation impairment during PCD

Translation is the final step in the flow of the genetic information, therefore a regulation at this level allows for an immediate response to changes in physiological conditions, such as cellular stress or activation of PCD, that require immediate changes in protein levels. To answer that, diverse adaptation strategies, as regulation of global translation combined with selective translation, have evolved providing rapid and reversible regulation of protein expression.

**Table 1** – Translation initiation factors alterations during PCD.

Translation initiation factor	Modification	References
eIF2 $\alpha$	Cleavage by caspase-3	[64, 65]
eIF2 $\alpha$	Ser <sup>51</sup> Phosphorylation	[66-73]
eIF3 (p35), eIF3b, eIF3f, eIF3g, eIF3k	Cleavage by caspase-3 or inhibition of activity by interaction with other protein	[65, 74-77]
eIF4B	Cleavage by caspase-3	[65]
eIF4E	Cleavage by caspase-3	[78-80]
4E-BP1	Cleavage by caspase-3	[65, 81]
eIF4GI and eIF4GII	Fragmentation by caspase-3 and caspase-8	[59, 65, 73, 82-87]
DAP5/p97	Reduced levels or cleavage by caspase	[88-92]

Over the last years, several studies have demonstrated that during PCD, translation initiation factors, mainly translation initiation factor 4G (eIF4G) family members [59, 65, 73, 82-87], but also translation initiation factor 2 $\alpha$  (eIF2 $\alpha$ ) [64, 65], 3 (eIF3) [65], 4B (eIF4B) [65], 4E (eIF4E) [78-80], DAP5/p97 [88-92]

and eIF4E binding proteins (4E-BP1) [65, 81], are targets of specific cleavage mediated by caspases in a variety of cell types and in response to different stimuli (Table 1). Moreover, post-translational modifications such as the phosphorylation of eIF2 $\alpha$  mediated by haem-regulated inhibitor kinase (HRI), protein kinase RNA (PKR), PKR-like endoplasmic reticulum kinase (PERK) or general control non-derepressible-2 (GCN2), lead to the reduction of the canonical cap-dependent translational initiation [66-73]. However, others mechanisms, such as the GCN4 translation by four upstream open reading frames (ORFs), firstly described in yeast, being induced by the phosphorylation of eIF2 $\alpha$  as a response to amino-acid starvation [93, 94] and cap-independent internal ribosome entry site (IRES)-mediated translation, which selectively recruits mRNAs harbouring IRES in their 5' untranslated region (5'UTR), have shown to be activated in order to fulfil the cellular requirements.

#### 1.2.2.1 IRES-mediated translation

IRES-mediated translation is a tightly controlled mechanism of translation of specific mRNAs regulated by their unique sequences in the 5'UTR, in conditions of global translation impairment such as stress and apoptosis. IRES are sequences with a high percentage of GC and several AUGs usually present in long 5' UTRs mRNAs but that can also be found in the mRNA coding sequence. These sequences form a complex secondary structure, which directly recruit ribosomes independently of the mRNA cap-structure and of the eIF4E [4]. However, no similarities between the structures or sequences of these cellular IRES were identified so far. Several canonical translation initiation factors may participate in the initiation of IRES-mediated translation. Different IRES-containing mRNAs have shown to require specific canonical translation initiation factors (Figure 3B) [4, 5, 95]. Furthermore, for an efficient IRES-mediated translation, auxiliary cellular proteins, known as IRES trans-acting factors (ITAFs), are also required [96]. These ITAFs can stimulate or inhibit the activity of IRES elements by affecting ribosome recruitment or modifying the structure of the IRES mRNA itself.

This alternative translation has proven to be an important regulatory mechanism for the organism homeostasis being associated both to survival or death of the cell.

### 1.2.2 Apoptotic regulators IRES-mediated translation during PCD

During the last decade, IRES sequences have been reported in the mRNA of proteins with important roles in cell growth, differentiation and regulation of PCD [4]. Example of this mechanism is the translation of several mammalian apoptotic regulators, both inhibitors and inducers of apoptosis (Figure 3).

Mammalian anti-apoptotic proteins, such as c-IAP1 [97], HIAP2 [98, 99] and the well described X-chromosome-linked inhibitor of apoptosis (XIAP) [99-108] are translated by an IRES-mediated mechanism blocking the apoptotic process through direct binding and inhibition of caspases activity. The contribution

**Figure 4** – IRES-mediated translation initiation regulates the expression of key apoptotic players, both pro-apoptotic and anti-apoptotic factors. From [4]

of pro-apoptotic proteins such as Apaf-1 [109-111], c-myc [112-117], DAP5 [91, 118] and p53 [119-121] for PCD is also regulated by IRES, leading to the activation of the apoptotic cascade. The balance between the relative levels of these apoptotic regulators will determine the cells fate, survival or cell death (Figure 3).

A role of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), a glycolytic enzyme, in the repression of p53 translation by direct binding to the p53 3'UTR has been described [134]. In mammalian cells, this enzyme is a known inhibitor of virus and mammalian mRNAs IRES-mediated translation [119, 134-138]. Hence, GAPDH is responsible for the inhibition/repression of cap-independent IRES-mediated translation in higher eukaryotes as a protective mechanism against opportunistic viral infections and apoptosis. Its specific cleavage by caspase-1 during apoptosis [139] might lead to the unblock of p53 IRES-mediated translation and ultimately to the apoptotic cell death.

Therefore, IRES-mediated translation is an important piece of the intricate puzzle that controls PCD and a deregulation of this process may lead cellular alterations.

### 1.3 HSP90 CHAPERONES AND PCD

HSP90 chaperones are highly conserved constitutively abundant proteins with crucial roles in protein folding/refolding as well as in the general response to stress and PCD [140-143]. Although HSP70 chaperones proved to be translated by IRES-mediated translation [125], and despite the overlapping functions of HSP70 and HSP90 [2, 144-149], a regulation of HSP90 chaperones translation at this level was never addressed. Prominent members of mammalian HSP90 family are the cytoplasmic chaperones Hsp90 $\alpha$  and Hsp90 $\beta$  [141, 142]. Hsp90 $\beta$  is expressed constitutively to a higher level than Hsp90 $\alpha$ , which is generally stress-inducible [141]. Unlike to other eukaryotic HSPs [150], the nucleotide sequence of HSP90 chaperones include several introns and exons, mainly in the 5' and 3'UTRs

**Figure 5** – HSP90 client proteins have a crucial role in PCD. Proteins marked in blue are anti-apoptotic proteins which stability is regulated by HSP90. Proteins marked in red are involved in the progression of PCD and are repressed by interaction with HSP90.

**Figure 6** – Modulation of apoptosis by HSP90 through interaction with client proteins. From [2].

[151, 152]. The differences in the amino acid sequence and the differential patterns of expression of Hsp90 $\alpha$  and Hsp90 $\beta$  isoforms raises the possibility of their interaction with distinct client proteins, being involved in different cellular functions. However, most of the studies do not differentiate the functions of HSP90 $\alpha$  and HSP90 $\beta$ . Despite this obstacle for the elucidation of HSP90 isoforms cellular functions, recent studies suggest that some functions of the HSP90 $\beta$  are not overlapped by HSP90 $\alpha$  [153, 154]. During oxidative stress induced by ascorbate/menadione, in mammalian cells only the HSP90 $\beta$  is cleaved leading to the reduction of the levels of its client proteins Bcr-Abl, RIP and Akt [153, 154].

Their function influences the activity and stability of a wide range of client proteins such as key regulators in cellular growth, differentiation and cell death pathways [155]. Hsp90 chaperones are responsible for the stability of anti-apoptotic proteins, such as: Survivin, IGF-IR, Cdc37, Zap-70, Bcr-Abl, IKK $\alpha/\beta$ , p53, Bcl-2 and AKT [143, 153, 156-166] and in the repression of pro-apoptotic proteins such as Apaf-1, Bid and FKBP38 [167-171] (Figure 5). In fact, the regulation of the Fas- and Tumor-necrosis factor receptor 1 necrotic process by mammalian HSP90 chaperones through the interaction with its client protein RIP1 has also been described [25, 172, 173]. Modulation of the HSP90 expression leads to cellular alterations. The overexpression of HSP90 induces cell survival and their depletion by siRNA or inhibition using geldanamycin triggers apoptosis [32, 160, 165, 172, 174-180]. The fact that Apaf-1 translation is tightly regulated by IRES and its contribution for the PCD process is under control of HSP90, is a good evidence that PCD is a complex process under the control of different sequential mechanisms and molecules and the smallest alteration in this process may lead to carcinogenesis.

Since HSP90 chaperones are powerful inhibitors of apoptosis, a modulation of their cellular levels affects the cellular homeostasis. In fact, HSP90 are the only chaperones targeted in cancer therapy, namely in anti-Acute Myeloid Leukemia (AML) treatment to sensitize tumor cells to chemotherapy-induced death through the use of HSP90 specific inhibitor geldanamycin [159, 181-185], [184, 186, 187]. However, the outcome of these treatments is below expectations, probably due to an undifferentiated inhibition of all the HSP90 isoforms therefore affecting the function of different client proteins in distinct molecular pathways [188].

## 1.4 Yeast PCD

For decades, the apoptotic process was assumed to occur only in multicellular organisms as a protective mechanism of rapid removal of unwanted or damaged cells that could otherwise inflame the surrounding cells with their cytoplasmic contents. This perception changed in 1997, when Madeo and coworkers showed that the yeast *Saccharomyces cerevisiae* also undergoes PCD

with typical apoptotic markers such as externalization of phosphatidylserine to the leaflet of the outer plasma membrane, degradation of DNA, condensation of chromatin, and production of reactive oxygen species (ROS) [189]. Several reports followed showing the occurrence of this process induced by diverse exogenous stimuli like  $H_2O_2$  [190] and acetic acid [191], the two most extensively studied apoptotic stimuli in yeast [3, 189, 191, 192], or by endogenous stimuli such as

**Figure 7** – Proteins and pathways regulating yeast apoptosis. From [3]

ating pheromones [193, 194] and aging [195, 196]. This was the starting point for the study of an old process in a new unicellular eukaryotic model. Scientist focused their attention on the molecular pathways and regulators controlling the apoptotic process searching for conserved mechanisms from yeast to mammalian cells. In fact, throughout this decade, the knowledge on the yeast apoptotic regulatory mechanisms had a massive development. Yeast apoptosis proved to be mediated by several orthologues of mammalian apoptotic regulators, both anti-apoptotic proteins such as Bir1p (XIAPp) [197] and Cdc48p (VCP) [189] and pro-

apoptotic proteins as Aif1p (AIF) [41], Nuc1p (endoG) [198], and Nma111p (HtrA2/Omi) [197] (Figure 7). Furthermore, a conservation of the molecular pathways involved in the regulation of the apoptotic process was also observed (Figure 7). The activation of an yeast caspase like protease, metacaspase [40], the mitochondrial membrane depolarization [199], release of cytochrome c from mitochondria to cytoplasm [199], mitochondrial fission and fusion [200, 201] and actin cytoskeleton alterations [202-204] support the conservation of the main apoptotic hallmarks of PCD from yeast to mammalian cells (Figure 7).

Over a decade ago, a family of proteases presenting structural similarities to caspases was identified in protists, fungi and plants [205]. These proteases were named metacaspases and classified, according to the presence or absence of a N-terminal prodomain containing a proline-rich repeat motif, as type I or type II, respectively. In spite of the structural similarity with the remotely related caspases, a large body of accumulating evidence shows that all metacaspases are highly specific for P1-Arg and P1-Lys substrates [206].

Yeast cells have a single gene, *YCA1*, encoding a type I metacaspase that was first implicated in the execution of oxidative stress induced cell death [40] but that is estimated to participate in approximately 40% of the described yeast apoptotic scenarios [207]. Nevertheless, non-death functions have also been assigned to yeast metacaspase such as cell cycle regulation [208] and protein catabolism [209]. Although the mechanisms regulating this multifunctional protein, metacaspase, still remain elusive, it is known that metacaspases activity is regulated through S-nitrosation and thus dependent on the endogenous levels of nitric oxide (NO) [210]. S-nitrosation of one metacaspase Cys residue keeps it inactive. However, a second catalytic Cys residue, highly conserved in all known metacaspases but absent in all members of caspases, can rescue metacaspase activity in the presence of high NO levels [210]. Accordingly, in yeast H<sub>2</sub>O<sub>2</sub>-induced apoptotic conditions [40, 190], a cell death process dependent on metacaspase activity and NO generation, metacaspase activity and cell death are abolished in the presence of L-NAME, an inhibitor of NO synthesis [211, 212].

One of the major mechanistic challenges for understanding the role of metacaspases in cell survival and death is still the identification of their natural

substrates. Until recently, the only protein known to be cleaved by metacaspases in vivo was the evolutionarily conserved TSN (Tudor *staphylococcal* nuclease) [213] found in all eukaryotes except in budding yeast [213]. Thus, although in yeast, metacaspase is essential for apoptosis execution upon a wide range of either physiological or external stimuli [40, 214], the substrates and therefore the specific molecular pathways targeted/regulated by this protease are still unknown.

#### 1.4.1 Acetic acid and H<sub>2</sub>O<sub>2</sub>: the paradigmatic inducers of yeast PCD

Over the last decade, diverse stimuli have been associated to the induction of yeast apoptosis. Among those stimuli, acetic acid and H<sub>2</sub>O<sub>2</sub> are the most studied and were used in most of the experiments presented in this thesis.

Although acetic acid is used as an external apoptotic stimulus, this compound is an end product of yeast alcoholic fermentation and could be considered as a natural physiological apoptotic stimulus. In the course of acetic acid apoptotic process, mitochondria appear to play a preponderant role. Acetic acid treatment leads to the production of ROS in mitochondria, induction of the mitochondrial membrane depolarization [199], release of cytochrome c to cytoplasm [199], translocation of Aif1p from mitochondria to the nucleus [41], leading to DNA fragmentation, culminating with the mitochondria fission and fusion [200]. Moreover, during acetic acid-induced apoptosis, a severe intracellular amino acid starvation occurs, leading to the inhibition of the target of rapamycin (TOR) and of protein phosphatases Pph21p and Pph22p, downstream mediators of TOR signaling [215], derepressing Gcn2p kinase and therefore leading to a cell cycle arrest in G0/G1 phase [215]. Proteomic analysis of acetic acid-treated cells also revealed a decrease in the levels of several translation factors, namely eIF4A, eEF1A, eEF2 and eEF3A [215]. Furthermore, an extensive degradation of ribosomal RNAs occurs during acetic acid-induced apoptosis [216]. These data together with the literature regarding the translation regulation of apoptosis in mammalian cells, strongly suggests a regulation of translation process during acetic acid induced-apoptosis. Despite the described degradation of mitochondria and ribosomal RNA during acetic acid treatment, a recent report demonstrated that

autophagy is not involved in the modulation of acetic acid-induced apoptosis [201]. Curiously, it is suggested that the yeast metacaspase, performs a role in the acetic acid-induced apoptosis, unrelated to its caspase activity [217].

During H<sub>2</sub>O<sub>2</sub>-induced apoptosis, a different apoptotic cascade appears to be activated, in which metacaspase plays a key role [40, 214, 218, 219], having high levels of activity [40]. Metacaspase participation in acetic acid-induced apoptosis is not as essential as in H<sub>2</sub>O<sub>2</sub>-induced apoptosis [217]. Moreover, alterations in the translation process also proved to contribute for the H<sub>2</sub>O<sub>2</sub>-induced apoptosis, such as the extensive degradation of ribosomal RNAs [216] and the decrease of global translation mediated by the phosphorylation of eIF2 $\alpha$  through Gcn2p kinase (the amino acid control kinase) [220].

Although the knowledge in the yeast apoptotic cell death has been greatly improved during the last years, establishing yeast as a good model for the study of PCD, the participation/conservation of some apoptotic mechanisms, such as the IRES-mediated translation, from yeast to mammalian was never addressed.

Nevertheless, similar to what occurs in mammalian cells, the occurrence of a PCD with typical necrotic features, such as the increase in cell volume (oncosis), swelling of organelles, DNA degradation and plasma membrane disruption with the loss of intracellular contents, has also been described in yeast [221]. Moreover, the nuclear release of yeast HMGB1 (Nhp6Ap) was considered a molecular marker of necrosis in yeast [222]. The balance between the occurrence of apoptotic or necrotic cell death upon acetic acid or H<sub>2</sub>O<sub>2</sub> treatment was previously reported to be determined, for the same period of treatment, by concentration, higher concentrations will lead to necrosis, while lower concentrations to apoptosis [190, 191]. This balance is important for the cellular homeostasis, therefore a methodical study of the mechanisms controlling this balance is of utmost importance.

In yeast, it has been reported that the inhibition of yeast HSP90, by radicicol, leads to the inhibition of tunicamycin-induced necrosis [223]. Yeast HSP90 family of chaperones, as well as their mammalian counterparts, are responsible for the protein folding/refolding, influencing the activity and stability of a wide range of client proteins that function as key regulators in PCD [142, 224]. These data

suggest a conservation of the molecular regulators of necrosis from yeast to mammalian cells. Nonetheless, no homologue of RIP1 in yeast is known, but other serine/threonine kinase, Slt2p, interacts with HSP90 [225, 226] and may have a role in the regulation of necrotic cell death.

#### 1.4.2 Translation control in yeast PCD

In yeast, few reports showed the involvement of translation control in PCD. A recent study in *S. cerevisiae* revealed that oxidative stress, by exposure to H<sub>2</sub>O<sub>2</sub>, causes a dose-dependent inhibition of translation through Gcn2 kinase (the amino acid control kinase) phosphorylation of eIF2, but that some mRNAs are still translated after oxidative stress [220]. Interestingly, our published results, using yeast *S. cerevisiae* as model, also showed that under acetic acid induced PCD, the

<b>YMR181c</b>	Protein of unknown function involved in invasive growth	[227]

expression of some translation factors such as eIF4A, eEF1A, eEF2 and eEF3A is diminished [215], but the levels of several other proteins, such as the HSP90 chaperones were increased [215]. These data, strongly suggests the existence of

an alternative IRES-mediated cap-independent mechanism regulating the translation of specific mRNAs upon the apoptotic stimulus, similar to what is described in mammalian cells [4, 5, 95, 235]. In yeast, IRES were mainly reported in transcriptional regulators involved in the response to yeast stress stimulus such as transcription factor *FLO8* required for invasive growth [227], transcription factor *YAP1* [234] and transcriptional activators *HAP4* [228] and *MSN1* [227], involved in the response to oxidative stress and transcriptional repressor of genes involved in nitrogen catabolism *URE2* [230] (Table 3). Moreover, during yeast nutrient starvation an eIF4G-dependent IRES-mediated cap-independent translation of several genes is required for invasive growth as a response to stress [227] (Table 3). However, the role of IRES in the regulation of yeast PCD phenomena has never been addressed.

The identification of the yeast apoptotic regulators capable of putative IRES-mediated translation during PCD would allow an integrated view of the signaling pathways that control the yeast life and cell death decisions.

This chapter attempts to summarize the relevant findings on the translation control of mammalian cells apoptotic processes and the information relative to a conservation of this regulation from yeast to mammalian cells. However, several questions concerning the control of the translation process and its contribution for the yeast apoptotic process remain to be answered. On the next chapters, results will be presented in an attempt to get new insights on the yeast translation regulation of apoptosis, through the study of translation machinery alterations, mRNAs capable of overcoming global translation impairment during apoptosis, as well as their role in the PCD processes, hoping to contribute for the continuous knowledge of the molecular regulatory mechanism controlling cell death.

## 2.1 ABSTRACT

The decrease of global mRNA translation efficiency during the progression of apoptosis in mammalian cells is a well recognized event [95]. In yeast a correlation between these two processes has also been observed, but the molecular basis of this regulation was never deeply explored. Our previous report revealed a downregulation of translation factors eIF4A, eEF1A, eEF2 and eEF3A levels during yeast acetic acid-induced apoptosis [215], suggesting an impairment of translation during the apoptotic process. In order to better understand the cascade of events leading to translation alterations upon acetic acid treatment, a thorough study of the translation process and of the changes induced by abrogation of one of its key described regulator, Gcn2p kinase [236-238], during acetic acid-induced apoptosis was studied. Polysome profiling kinetic analysis showed a premature dose-dependent reduction of cap-dependent translation initiation correlated with the phosphorylation of eIF2 $\alpha$  by Gcn2p kinase, and a later inhibition of translation elongation. Furthermore, Gcn2p kinase proved to be a crucial player in acetic acid-induced apoptosis, due to the more resistant phenotype displayed by *GCN2* deleted cells and the severe reduction of eIF2 $\alpha$  phosphorylation. Nevertheless, RT-PCR analysis of polysomal fractions revealed that some mRNAs, such as the pro-apoptotic factor *AIF1*, are translated under these conditions, suggesting the activation of an alternative translation process. Altogether, these results demonstrate that translation regulation is an important component of the cellular response to acetic acid-induced apoptosis.

## 2.2 INTRODUCTION

Although apoptosis is a phenotypical well characterized programmed cell death (PCD) process, the complete uncover of the molecular pathways underneath this phenomenon is a continuous challenge. The involvement of the translation process in the regulation of apoptosis is a still emerging concept [95, 96, 239-243]. In mammalian cells, global cap-dependent translation proved to be reduced during the progression of apoptosis [95] due to mRNA 5' decapping and specific fragmentation of translation factors, mainly the translation initiation factor 4G (eIF4G) family members [59], mediated by caspases. Besides caspases, other pro-apoptotic proteins were associated to the regulation of translation factors during apoptosis, such as the apoptosis-inducing factor AIF, which binds to the eIF3g during the apoptotic stimulus blocking translation [76]. Post-translational modifications of translation initiation factors, such as, phosphorylation of subunit  $\alpha$  of translation initiation factor 2 (eIF2 $\alpha$ ) were also described [59]. However, the involvement of translational control in yeast PCD is still scarce. The deletion of *LSM4* gene, involved in yeast mRNA decay, inhibits mRNA decapping leading to an increase in mRNA stability and ultimately triggering a caspase-dependent apoptotic process [244-246]. Furthermore, an extensive degradation of ribosomal RNAs is observed during H<sub>2</sub>O<sub>2</sub>- and acetic acid-induced apoptosis and a decrease of global translation due to the phosphorylation of eIF2 $\alpha$  by Gcn2p kinase (the amino acid control kinase) also occurs during oxidative stress [220]. In fact, Gcn2p appears to play a crucial role in the regulation of distinct cellular processes. Apart from its role in the regulation of translation initiation through eIF2 $\alpha$  phosphorylation, this kinase has been related to the control of cell cycle, through a DNA damage checkpoint between G1 and S phase [247, 248], being also involved in the TOR-mediated activation of autophagy [249]. Previously, we have shown by proteomic analysis that during acetic acid-induced apoptosis, a severe intracellular amino acid starvation occurs [215] and the levels of translation initiation factor 4A (Tif1/2p) and translation elongation factors 1A (Tef1/2p), 2 (Eft1/2p) and 3A (Yef3p) were decreased [215] suggesting an impairment of translation during yeast apoptosis regulation. Herein we show the occurrence of translation alterations

during the execution of acetic acid-induced apoptosis and disclose the involvement of the known translation regulator, Gcn2p kinase, in this process.

## 2.3 MATERIALS AND METHODS

### Strains, media and treatments

*Saccharomyces cerevisiae* strain BY4742 (*MAT $\alpha$  his3 $\Delta$ 1 leu2 $\Delta$ 0 lys2 $\Delta$ 0 ura3 $\Delta$ 0*) and its isogenic derivatives  *$\Delta$ tif1*,  *$\Delta$ eft1*,  *$\Delta$ gcn2* and  *$\Delta$ aif1* (EUROSCARF, Frankfurt, Germany) were used. For acetic acid treatment, *S. cerevisiae* cells were grown until the middle exponential phase in liquid YPD medium containing glucose (2%, w/v), yeast extract (0.5%, w/v) and peptone (1%, w/v) at 26°C (150 r.p.m.). Cells were initially harvested, resuspended in fresh medium (pH 3.0) and incubated at 26°C for 1h. Afterwards, cells were resuspended ( $10^8$  cells/mL) in fresh medium (pH 3.0) followed by the addition of 180, 195, 210 or 225 mM of acetic acid and incubated during 15, 30, 60, 120 and 200 min at 26°C with stirring (150 r.p.m.), with or without the presence of 2.5 mM chloroquine, 1.1  $\mu$ M rapamycin and 2% threalose (in this condition glucose is not added to the YPD medium). After the 200 min treatment, approximately 300 cells were spread on YPD agar plates and viability was determined by counting colony forming units after 2 days of incubation at 26°C [199]. Cells were also harvested for further studies described below.

### Protein synthesis analysis

Protein synthesis was analysed in cells exposed to 195 mM of acetic acid during 15 min. Cultures were labelled with 85  $\mu$ M L-[ $^{35}$ S] methionine during the last 5 min of the acetic acid treatment, and 100  $\mu$ g/mL cycloheximide (CHX) was just added before harvesting the cells. Total protein extracts were resolved by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), as described below, and either the gels were stained with Coomassie blue or protein extracts were detected by enhanced chemiluminescence.

### **Polysome profile analysis**

Yeast cells were grown to middle exponential phase and treated with acetic acid as described above. Five minutes before cells being harvested, CHX was added to a final concentration of 100  $\mu\text{g/mL}$ , cells were collected, washed with cold phosphate-buffered saline (PBS) and disrupted using lysis buffer [20 mM Tris (pH 8.0), 140 mM KCl, 1.5 mM  $\text{MgCl}_2$ , 0.5 mM DTT, 1 mM PMSF, 100  $\mu\text{g/mL}$  CHX] and glass beads (Sigma). 40 units  $A_{280\text{nm}}$  were loaded onto 11 mL 15 - 50 % sucrose gradients containing 20 mM Tris-HCl at pH 8.0, 140 mM KCl, 5 mM  $\text{MgCl}_2$ , 0.5 mM DTT, 100  $\mu\text{g/mL}$  CHX and 500  $\mu\text{g/mL}$  heparin. Gradients were centrifuged using a SW41 rotor (Beckman-Coulter) at 35000 rpm for 2 hours and 45 min at 4°C. Polysomal profiles were visualized by monitoring RNA absorbance at 254nm using a Bio-Rad Biologic LP system adapted for this use. Monosomal and polysomal fractions of the gradient were collected into tubes containing 8M guanidine-HCl, ethanol was added to a final concentration of 50% and fractions were stored at - 80 °C.

### **Polysomal RNA preparation**

Polysomal mRNA was precipitated with ethanol 85%, extracted using phenol: chloroform and precipitated, first with 1.5 M lithium chloride (LiCl) for removing any residual heparin, and then with 100% ethanol plus 110 mM sodium acetate, pH 5.3.

### **RT-PCR analysis**

Total RNA was isolated from monosomal and polysomal fractions. For quantitative reverse transcription polymerase chain reaction (RT-PCR), reverse transcription of RNA to cDNA was carried out using the First-Strand cDNA synthesis kit (GE Biosciences). The quantitative PCR was performed on a Stratagene Mx3005PTM real-time thermocycler using EVAGreen (Bio-Rad) and gene-specific primers as described in Table 4.

Relative expression levels were determined using the standard curve method. Controls lacking reverse transcriptase (RT) demonstrated no significant genomic DNA amplification.

**Table 4** - List of primers for quantification of mRNA expression by RT-PCR and their efficiency (Eff).

### Assessment of intracellular reactive oxygen species

Free intracellular reactive oxygen species (ROS) were detected with dihydrorhodamine 123 (DHR123) (Molecular Probes). DHR123 was added from a 1 mg/mL stock solution in ethanol to  $5 \times 10^6$  cells/mL suspended in PBS, reaching a final concentration of 15  $\mu$ g/mL. Cells were incubated for 90 min at 30°C in the dark, washed in PBS and analyzed by flow cytometry. Flow cytometric assays were performed on a BD LSR II™ (Becton Dickinson, NJ, USA) using BD FACSDiva Software 6.0 (Becton Dickinson, NJ, USA). Twenty thousand cells per sample were analyzed using the FlowJo software (Tree Star, Ashland, OR, USA). Data express the percentage of DHR123-positive cells compared to the total number of counted cells.

### Immunoblot analysis

For detection of protein levels in total cellular extracts, untreated or acetic acid-treated cells (195 Mm) were collected and disrupted using glass beads in lysis buffer [1% v/v Triton X-100, 120 mM NaCl, 50 mM Tris-HCl pH 7.4, 2 mM EDTA, 10% v/v Glycerol, 1 mM PMSF and Complete Mini protease inhibitor

cocktail (Roche, Mannheim, Germany)]. From total protein extracts, 40  $\mu$ g (100  $\mu$ g for the protein synthesis analysis assay) were resolved on a 12% SDS-PAGE gel and transferred to a nitrocellulose membrane (Amersham) over 90 min at 100 V. Membranes were then probed with polyclonal rabbit Ser51 phosphorylated eIF2 $\alpha$  (Sui2p) antibody (1:2000, Upstate), polyclonal rabbit anti-eIF2 $\alpha$  (1:2000, Cell Signaling Technology), polyclonal rat anti-eIF4G (Tif4631/Tif4632p) (1:1000, kindly provided by Michael Altmann), polyclonal rabbit anti-eEF2 (Eft1/2p) (1:15 000), polyclonal rabbit anti-eEF1A (Tef1/2p) (1:15 000, both antibodies were kindly supplied by Prof. T.G. Kinzy), polyclonal rabbit anti-eIF4A (Tif1/2p) (1:15 000, kindly supplied by Prof. M. Montero-Lomelí) and polyclonal goat anti-actin (1:5000, kindly provided by Prof. Campbell Gourlay). Horseradish peroxidase (HRP)-conjugated anti-rabbit, anti-rat and anti-goat IgG secondary antibody were used, at a dilution of 1:5000 and detected by enhanced chemiluminescence.

### **Cell cycle analysis**

Cell-cycle analysis was performed in wild-type and  $\Delta$ *gcn2* untreated and 195 mM acetic acid-treated cells after 200 min of treatment. Cells were harvested, washed and fixed with ethanol (70% v/v) at 4°C. Following, cells were sonicated, treated with RNase for 1 h at 50°C in sodium citrate buffer (50 mM sodium citrate, pH 7.5), and subsequently incubated with proteinase K (0.02 mg per 10<sup>7</sup> cells). Cellular DNA was then stained overnight at 4°C with SYBR Green 10000X (Molecular Probes), diluted tenfold in Tris-EDTA (pH 8.0). Samples were then diluted 1:4 in sodium citrate buffer, sonicated and analyzed by flow cytometry as described in [215]. Determination of cells in each phase of the cell cycle was performed offline using MODFIT LT 3.2 software (Verity Software House, Topsham, ME).

### **Vacuolar membrane staining**

FM 4-64 (*N*-(3-Triethylammoniumpropyl)-4-(6-(4-(Diethylamino)phenyl)hexatrienyl) Pyridinium Dibromide, Molecular Probes Inc., Eugene, OR) staining was performed as described [250]. Prior to staining, wild-type and  $\Delta$ *gcn2* cells expressing GFP-Atg8 (pRS416-GFP-Atg8 plasmid was kindly

provided by F. Reggiori) were cultured overnight in YPD medium, harvested during mid-logarithmic phase, pre-incubated for 1h in YPD (pH 3.0) and treated for 200 min in YPD (pH 3.0) with 195 mM of acetic acid. For FM 4-64 staining, cells were harvested and resuspended in fresh YPD medium. FM 4-64 was added to 25  $\mu$ M from a stock solution of 16 mM in DMSO. The cells were then incubated with shaking for 10-15 min at 30°C. After this preliminary labelling step, the cells were harvested at 700 g for 3 min at room temperature, resuspended in fresh YPD medium and incubated with shaking for 60 min. Afterwards, the cells were harvested, resuspended in fresh YPD medium, placed on standard slides, and visualized by epifluorescence microscopy with an Olympus BX61 microscope equipped with a high-resolution DP70 digital camera and with an Olympus UPlanSApo 100X/oil objective, with a numerical aperture of 1.40.

### **Preparation of protein extracts for 2-D gel electrophoresis (2-DE)**

For preparation of total cellular extracts, untreated and acetic acid-treated wild-type and  $\Delta gcn2$  cells (195 and 270 mM) were collected and disrupted using glass beads in lysis buffer [1% v/v Triton X-100, 120 mM NaCl, 50 mM Tris-HCl pH 7.4, 2 mM EDTA, 10% v/v Glycerol, 1 mM PMSF and Complete Mini protease inhibitor cocktail (Roche, Mannheim, Germany)]. Protein concentrations were determined with a commercially available kit (RotiNanoquant, C. Roth, Karlsruhe, Germany) and protein aliquots (100  $\mu$ g, 600  $\mu$ g) stored at -20°C. To verify the reproducibility, three independent samples from total cellular extract were obtained for each of the three conditions (control and 195 and 270 mM acetic acid-treated cells) and each sample separated within four 2-DE gels.

### **2-DE**

For 2-DE the protein pellet was resuspended in urea buffer (8 M urea, 2 M thiourea, 1% [w/v] CHAPS, 20 mM DTT, 0.8% [v/v] carrier ampholytes and Complete Mini protease inhibitor cocktail). The protein separation was done as previously described [164]. Briefly, the protein solution was adjusted with urea buffer to a final volume of 350  $\mu$ L and in-gel rehydration was performed over night. Isoelectric focusing (IEF) was carried out in IPG strips (pH 3–10, non linear, 18

cm; GE Healthcare, Uppsala, Sweden) with the Multiphor II system (GE Healthcare) under paraffin oil for 55 kVh. SDS-PAGE was done overnight in polyacrylamide gels (12.5% T, 2.6% C) with the Ettan DALT II system (GE Healthcare) at 1-2 W per gel and at 12°C. The gels were silver stained and analyzed with the 2-DE image analysis software Melanie 3.0 (GeneBio, Geneva, Switzerland). The apparent isoelectric points (pI) and molecular masses (Mr) of the proteins were calculated with Melanie 3.0 (GeneBio) using identified proteins with known parameters as a reference. An expression change was considered significant if the intensity of the corresponding single spot differed reproducibly more than two-fold and was reproducible for all three experiments.

### **Identification of altered proteins by mass spectrometry**

To identify low abundant proteins, the spots were excised from 2-D gels separated with 600 µg of protein, in-gel digested, and identified from the peptide fingerprints as described elsewhere [251]. Proteins were identified with the ProFound database, version 2005.02.14 (<http://prowl.rockefeller.edu/prowl/cgi/profound.exe>) using the following parameters: 20 p.p.m.; 1 missed cut; MH+; +C2H2O2@C (Complete), +O@M (Partial). The identification of a protein was accepted if the peptides (mass tolerance 20 p.p.m.) covered at least 30% of the complete sequence. Sequence coverage below 20% was only accepted if at least three main peaks of the mass spectrum matched with the sequence and the number of weak-intensity peaks was clearly reduced. If the protein spot was detected at a lower molecular mass than expected, which indicates processing or fragmentation, the spot-specific peptides in the mass spectrum were also analyzed to confirm which parts of the corresponding protein sequence matched with these peptides. If the mass spectrum of the spot lacked peptides observed for the complete protein it was indicated as a protein fragment. Therefore, both the spot position observed by 2-DE and the specific peptides in the corresponding mass spectrum were analyzed to indicate a putative protein fragment.

## Statistical analysis

Arithmetic means of ROS production and cell survival rates are presented with standard deviation with a 95% confidence value. Statistical analysis was carried out using independent samples *t*-test analysis. A *p*-value <0.05 was assumed to denote a significant difference.

## 2.4 RESULTS

### 2.4.1 Global translation impairment triggered by acetic acid

Our previous work on the proteomic profile of acetic acid apoptosing cells has shown that translation is severely affected, indicating a failure of the protein synthesis machinery in these conditions [215]. To further elucidate the regulation of protein synthesis, the translation alterations occurring during acetic acid treatment were assessed. Although acetic acid-induced apoptosis is a paradigmatic scenario to study yeast cell death [41, 191, 199, 215, 252], a scale-up condition of acetic acid treatment for the induction of apoptosis in approximately 50% of the wild-type exponential *S. cerevisiae* cells was optimized. This scale-up allowed to collect high amounts of total cellular extracts and to isolate enough RNA to perform polysome profile studies and to evaluate the role of translation in this process. Results showed that 195 mM of acetic acid induces about 50% of apoptotic cell death upon 200 min treatment and this was the concentration selected for the studies herein described (Figure 8A). In a first approach to evaluate the rate of translation process during acetic acid treatment, the incorporation of L-<sup>35</sup>[S] methionine in the yeast cells was analyzed. After 15 min of acetic acid treatment, and even though the same amount of protein was loaded, as shown by Coomassie blue staining (Figure 8B), no protein synthesis was detected by chemiluminescence in total protein extracts of treated cells. This result suggests that L-<sup>35</sup>[S] methionine was unable to enter the cells (Figure 8B) and supports our previously published data suggesting the blockage of amino acid uptake in acetic acid treated cells, leading to a severe cellular amino acid starvation [215]. Thus, translation alterations during acetic acid-induced apoptosis were assessed. For such purpose, the polysomal profile of wild-type cells treated with two different acetic acid

**Figure 8** - Global translation impairment during acetic acid-induced apoptosis. (A) Kinetic analysis of the survival rate of wild-type *S. cerevisiae* cells untreated and treated with 195 mM of acetic acid. (B) Protein synthesis analysis of wild-type *S. cerevisiae* cells in the absence or presence of 195 mM of acetic acid during 15 min. Cultures were pulse-labelled with [ $^{35}$ S] methionine during the final 5 min of the acetic acid treatment, and protein levels were analysed by SDS-PAGE. (C) Polysome profile of yeast cells treated with the indicated concentrations of acetic acid for 15 min. The peaks containing the small ribosomal subunit (40S), the large ribosomal subunit (60S), and both subunits (80S) are indicated.

concentrations (180 and 195 mM) was obtained. This analysis revealed an impairment of global translation in acetic acid treated cells, as reflected by the decrease of the polysomal fraction (corresponding to the polypeptide chains that are being actively assembled) and the increase of the monosomal fraction (corresponding to the small, large and both ribosomal subunits, 40s, 60s and 80s, respectively) (Figure 8C). This effect was shown to be dependent on the acetic acid concentration tested as cells treated with the highest concentration (195 mM) displayed a pronounced decrease of the polysomal fraction (Figure 8C). The impact of acetic acid on translation efficiency was further addressed by a kinetic analysis

**Figure 9** – Translation impairment increases throughout the 200 min of acetic acid treatment. (A) Statistic analysis of the percentage of total mRNA present in the polysomal fractions in the absence or presence of 195 mM of acetic acid during 0, 15 and 60 min. (B) Kinetic analysis of the polysomal profile of wild-type cells treated with or without 195 mM of acetic acid reveals a gradual and non transient translation impairment.

of polysome profile in association with the kinetic analysis of cell viability throughout the 200 min of treatment with 195 mM acetic acid (Figure 8A, 9). The acetic acid concentration selected (195mM) induced a progressive decline of survival along the treatment time course, compatible with a first response to the imposed stress and a later activation of the apoptotic cell death. At 200 min of acetic acid treatment, a heterogeneous population where 40% of cells are still coping with stress but 60% have lost the proliferative capacity is observed (Figure 8A). The analysis of polysome profile showed a decrease in the percentage of polysomes in acetic acid treated cells after 15 min that was aggravated at 60 min (Figure 9A). The impairment of translation was also confirmed by the observation of a decrease in the polysomal fraction and an increase in the monosomal fraction of acetic acid treated cells that was maintained and exacerbated throughout the 200 min of acetic acid treatment (Figure 9B).

These results showing that acetic acid affects both the initiation and the elongation steps of translation leading to a drastic reduction of the translation process efficiency raised three important questions: the cells are not able to recover from the acid stress imposed, translation control is an important event during the process of acetic acid-induced apoptosis, or both.

#### 2.4.2 Translation impairment induced by acetic acid is mediated by alterations in translation machinery

The observation of global translation impairment upon acetic acid-induced apoptosis prompted us to investigate the cascade of events leading to this alteration. Thus, we decided to perform a kinetic analysis of the protein levels of the translation initiation factors 4A (eIF4A/Tif1/2p) and 4G (eIF4G/Tif4631/2p) and

**Figure 10** - Global translation impairment during acetic acid-induced apoptosis is mediated by translation factors downregulation and post-translational modifications. (A) Immunoblot kinetic analysis of eIF2α (Sui2p) phosphorylation and translation initiation factors eIF2α (Sui2p), eIF4A (Tif1/2p) and eIF4G (Tif4631/2p) and translation elongation factors eEF1A (Tef1/2p) and eEF2 (Eft1/2p) levels in wild-type *S. cerevisiae* cells upon treatment with or without (untreated) 195 mM of acetic acid. Actin was used as loading control. (B) Survival assay of wild-type, *TIF1* and *EFT1* deleted strains upon acetic acid treatment. (C) Percentage of wild-type, *Δtif1* and *Δeft1* cells exhibiting high levels of intracellular ROS detected by FACS measurements of the dihydrorhodamine 123 fluorescence. \* $p \leq 0.05$  versus control, *t*-test,  $n=3$ .

and of the elongation factors 1A (eEF1A/Tef1/2p) and 2 (eEF2/Eft1/2p), previously shown in our proteomic analysis to be decreased upon acetic acid challenge [215]. The phosphorylation status of the translation initiation factor 2 $\alpha$  (eIF2 $\alpha$ /Sui2p) was also determined due to its well-known role on translation regulation [236, 253-256]. Immunoblot analysis revealed that just after 15 min of acetic acid treatment, the previously shown impairment of translation was correlated to alterations in translation initiation (Figure 10A). An increase in the levels of phosphorylated eIF2 $\alpha$  and a decrease in the levels of eIF4A (Figure 10A), suggested an impairment in the assembly of the translation initiation complex, crucial for the cap-dependent translation initiation [237], leading to a translation initiation impairment at early points of acetic acid treatment. The decrease in the levels of the elongation factors eEF1A and eEF2 and of the initiation factor eIF4G (a subunit of the mRNA cap-binding protein complex [237] was observed only at 120 min (Figure 10A). The concurred decrease of these translation factors at the same time point suggests that the drastic impairment of translation elongation only occurs after about 120 min (Figure 10A). These findings, together with the knowledge that eIF4G plays a role in yeast and mammalian internal ribosome entry site (IRES)-mediated translation [59, 82, 90, 227, 257-259] and that eEF1A increases the efficiency of the yeast IRES-mediated translation [232], raises the hypothesis that a minor selective translation mediated by cap-independent mechanisms might occur during acetic acid treatment.

In order to assess the relevance of the above described translation factors for the modulation of the apoptotic process induced by acetic acid a survival assay with the respective deleted strains was performed. Deletion of *SUI2* (eIF2 $\alpha$ ) and *TIF4631/2* (eIF4G) genes lead to unviable strains and a reliable *TEF1/2* (eEF1A) deleted strain is not available thus, we evaluated the resistance of *TIF1* (eIF4A) and *EFT1* (eEF2) deleted strains to acetic acid treatment (Figure 10B). Despite the fact that during acetic acid-induced apoptosis a decrease in the levels of both Tif1p and Eft1p is observed, the disruption of the respective genes leads to an increased resistance to acetic acid (Figure 10B). The deleted cells also displayed low reactive oxygen species (ROS) levels when compared to wild-type treated cells (Figure 10C). These results suggest that the alterations occurring in the translation process

during acetic acid treatment are also contributing to the apoptotic process. Thus, the control of the translation process upon acetic acid treatment appears to be crucial to determine the fate of the cells treated with acetic acid.

### 2.4.3 Gcn2p kinase modulates translation initiation impairment induced by acetic acid

Gcn2p is the only kinase described to be responsible for the phosphorylation of eIF2 $\alpha$  in yeast [253, 256, 260, 261]. Due to the observed increased levels

**Figure 11** - Gcn2 kinase modulation of translation alterations during acetic acid-induced apoptosis. (A) Comparison of the survival rate of wild-type and  $\Delta gcn2$  *S. cerevisiae* cells upon treatment with the indicated concentrations of acetic acid; \* $p \leq 0.05$  versus wild-type, *t*-test,  $n = 3$ . (B) Immunoblot kinetic analysis of eIF2 $\alpha$  (Sui2p) phosphorylation levels, translation initiation factors eIF2 $\alpha$  (Sui2p), eIF4A (Tif1p) and eIF4G (Tif4631/2p) and translation elongation factors eEF1A (Tef1/2p) and eEF2 (Eft1/2p) levels in  $\Delta gcn2$  *S. cerevisiae* cells upon treatment with or without (untreated) 195 mM of acetic acid. Actin was used as loading control. (C) Polysomal profile of *GCN2*-disrupted yeast cells treated with the indicated concentrations of acetic acid for 15 min.

of eIF2 $\alpha$  phosphorylated (Figure 10A), we decided to study the role of Gcn2p in the regulation of translation during acetic acid treatment. Thus, the resistance of the respective deleted strain to acetic acid treatment was studied. A more resistant phenotype of the *GCN2* deleted cells was observed, when compared to the wild-type cells (Figure 11A), associated with a drastic decrease in the phosphorylation levels of eIF2 $\alpha$ , observed by immunoblot analysis (Figure 11B). Nevertheless, phosphorylation of eIF2 $\alpha$  was detected in the first time points of acetic acid treatment (Figure 11B) suggesting the presence of other undisclosed kinases capable of its phosphorylation. Abrogation of *GCN2* also elicited an efficient translation as reflected by the levels of translation factors eIF4A, eIF4G, eEF1A and eEF2 (Figure 11B) and by the polysomal profile analysis (Figure 11C). These findings showed that acetic acid treatment leads to an impairment of translation initiation mainly regulated by the phosphorylation of eIF2 $\alpha$  under the control of Gcn2p kinase. Disruption of *GCN2* turns cells resistant to acetic acid, a phenotype associated with the recovery of translation competence. These data implicate the control of translation by Gcn2p in the progression of cell death induced by acetic acid.

Besides Gcn2p involvement in the regulation of protein synthesis, this kinase has also been described as a cell cycle regulator of cells exposed to ultraviolet (UV) irradiation through a Gcn2-dependent checkpoint which delays cells entry into S phase [247]. In fact, when we analyzed the cell cycle profile of wild-type cells after acetic acid treatment, an arrest in the G0/G1 phase was observed [215]. However, in the *GCN2* deleted strain this arrest in G0/G1 was alleviated (Figure 12A), suggesting that upon acetic acid treatment, the control of cell cycle related alterations, is under the regulation of Gcn2p kinase. Gcn2p is under control and repression by the target of rapamycin (TOR) pathway, responsible for the sensing of amino acid [237, 262-264], which was found to be inhibited during acetic acid-induced apoptotic cell death [191, 215, 218]. It is well known that amino acid starvation-induced inhibition of TOR leads to induction of autophagy [265-272] through Gcn2p-dependent activation of Atg8p and Atg4p autophagic components [249]. Since our previous data showed that acetic acid-induced a severe intracellular amino acid depletion [215], a role for autophagy in this cell death

process was addressed despite the recent report that autophagy is not involved in acetic acid-induced apoptosis [201]. Atg8p (homologous to the mammalian LC3 autophagic marker protein) is a phosphatidylethanolamine-conjugated ubiquitin-like protein required for the formation of autophagosomes and a key molecular component of the autophagic process [273]. The analysis of the mRNA expression levels of *ATG8* revealed a slight increase in *ATG8* mRNA levels in wild-type cells after 200 min of incubation, both untreated and acetic acid treated cells, when compared to *GCN2* disrupted cells (Figure 12B). To further assess the role of autophagy, wild-type and  $\Delta gcn2$  cells were transformed with a plasmid expressing the Atg8p tagged with GFP and the cellular vacuoles were marked with a fluorescent dye which binds to the vacuolar membrane (FM 4-64). After acetic acid treatment we observed a discrete increase in the levels of GFP-Atg8p and its localization in the internal membrane of the vacuole in the wild-type-treated cells. In *GCN2* deleted cells GFP-Atg8p was not found in the vacuoles (Figure 12C) and a diffuse green fluorescence, corresponding to the GFP-Atg8p, was observed all over the cell (Figure 12C). These results indicate that, as previously reported [249], in *GCN2* deleted cells autophagy is abrogated. However, some activation is observed in wild-type treated cells. To further address the role of autophagy, a pharmacological modulation of the autophagic process during acetic acid-induced apoptosis was performed and the survival rate of wild-type and *GCN2* deleted cells was assessed. For the inhibition of the autophagic process we used chloroquine which raises the lysosomal/vacuole pH leading to the inhibition of lysosome/vacuole-autophagosome fusion and lysosomal/vacuole protein degradation [274-278]. The induction of autophagy was achieved through a TOR-dependent pathway, using rapamycin [265, 267-270, 272, 279], and by a TOR-independent pathway using trehalose [280-282]. In wild-type acetic acid-treated cells, the inhibition of the lysosome/vacuole-autophagosome fusion by chloroquine led to a more pronounced cell death (Figure 12D). This result corroborates the previous observed colocalization of GFP-Atg8p with the vacuoles (Figure 12C), and suggests that upon acetic acid stimulus, activation of autophagy might be an important stress response mechanism. The incubation of the cells with acetic acid and rapamycin produced no synergistic effect (Figure 12D), most probably due to

**Figure 12** - The role of cell cycle and autophagy regulation by Gcn2p during acetic acid-induced apoptosis. (A) Analysis of the percentage of cells in each phase of the cell cycle in wild type and *GCN2* deleted cells untreated or upon 200 min of acetic acid treatment (195 mM). (B) Normalized relative expression levels of *ATG8* mRNA (*ACT1*, *TDH2*, *PDA1* and *TUB1* as internal references) in wild-type and  $\Delta gcn2$  cells. (C) Image of wild-type and  $\Delta gcn2$  cells harboring a plasmid expressing the GFP-Atg8 protein and colocalization with the vacuoles stained with a fluorescent dye (FM 4-64). (D) Comparison of the survival rate of wild-type and  $\Delta gcn2$  *S. cerevisiae* cells upon treatment with 195 mM acetic acid in the presence of 2.5 mM chloroquine, 1.1  $\mu$ M rapamycin or 2% trehalose. \* $p \leq 0.05$  versus wild-type, *t*-test,  $n = 3$ .

the repression of TOR pathway promoted by acetic acid [215]. Autophagy induction by a pathway independent of TOR, and therefore independent of Gcn2p kinase, increased survival (Figure 12D) suggesting that during acetic acid-induced apoptosis the activation of a TOR pathway-independent autophagy might play a protective role. Results showed that the manipulation of the autophagic process, even at a basal level, induces different responses in wild-type cells to acetic acid treatment (Figure 12D). The fact that the inhibition of autophagy increased cell death and induction of autophagy protected from cell death mediated by acetic acid was a good evidence of the involvement of autophagy in the cell's response to acetic acid treatment as a pro-survival mechanism. Nevertheless, *GCN2* disrupted cells, showing low levels of *ATG8* mRNA (Figure 12B), displayed an increased resistance to acetic acid treatment in the presence of both inhibitor and inducers of the autophagic process (Figure 12D). These data showed that Gcn2p role in acetic acid-induced apoptosis is related with the control/repression of cell cycle and cap-dependent translation initiation, and not with the regulation of the autophagic process, being an important player in the cellular response to acetic acid. In fact, the pro-survival effect of autophagy during acetic acid treatment appears to be under the control of other pathways besides TOR pathway.

#### 2.4.4 Proteomic analysis of *AIF1* deleted cells revealed alterations in translation factors upon acetic acid treatment

In mammalian cells a regulation of translation initiation by the apoptosis-

**Figure 13** – Survival assay for the optimization of the ideal acetic acid concentration for the induction of about 50% of cell death in wild-type and *AIF1* deleted strain.

**Figure 14** – Proteomic profile analysis of the acetic acid-induced Aif1p-independent apoptotic process. Representative silver-stained 2-D gel of total protein extracts wild-type and  $\Delta aif1$  cells untreated and treated with 195 or 270 mM of acetic acid. Spots altered upon acetic acid treatment are represented by numbers (1 – 132).

inducing factor (AIF), homologous to yeast Aif1p, through interaction with subunit p44 of translation initiation factor 3 (eIF3g) has been described [76]. Since in yeast, Aif1p is a crucial player during acetic acid-induced apoptosis [41, 283-285], we decided to evaluate the proteomic profile of  $\Delta aif1$  cells using two different concentrations of acetic acid capable of inducing about 50% of apoptotic cell death in wild-type (195 mM) and in the more resistant *AIF1* deleted cells (270 mM) (Figure 13). By comparing the total cellular proteome of untreated and acetic acid- treated cells both in wild-type and *AIF1* deleted cells, several spots were

**Figure 15** – Deletion of *AIF1* gene does not prevent alterations in translation machinery when cells are challenged with acetic acid. Enlarged 2-D gel parts represent altered proteins in total cellular extracts from wild-type and  $\Delta aif1$  untreated and treated (195 mM and 270 mM acetic acid) yeast cells.

found affected (Figure 14). Among them 10 spots related with the translation process showed decreased intensity (Figure 15). Mass spectrometry analysis revealed that 1 spot corresponded to eEF1A (Tef1/2p), 3 spots to eIF4A (Tif1/2p) and 6 spots to eEF3A (Yef3p) (Figure 15), previously described as down-regulated in wild-type cells [215]. No differences in the levels of translation initiation and elongation factors were found comparing the proteomic profile of wild-type and

*Δaif1* acetic acid treated cells. In fact, the treatment of *AIF1* deleted cells with 195mM or 270 mM of acetic acid, the later inducing 50% of cell death in *Δaif1* cells (Figure 13), revealed a decrease in the levels of translation factors eIF4A, eEF1A and eEF3A in both conditions (Figure 15). Results showed that translation machinery alterations are maintained in the absence of *AIF1*, suggesting that these alterations are independent of *AIF1* and therefore Aif1p does not have a role in the regulation of translation during acetic acid treatment.

#### **2.4.5 Evaluation of apoptotic regulators translation during acetic acid-induced apoptosis.**

In mammalian cells, after an apoptotic stimulus, cap-dependent translation process is reduced [95, 243]. However, it has been reported that several apoptotic regulators, both inhibitors and inducers of apoptosis such as XIAP and Apaf-1, respectively [109, 132], are capable of being translated by an alternative mechanism, a selective cap-independent translation mechanism [95]. In yeast, cap-independent translation has also been described [227, 230], however, its occurrence in an apoptotic condition was never addressed. Based on the results described above and in the knowledge that the inhibition of translation elongation by cycloheximide prevents acetic acid-induced apoptosis [199], we hypothesized that although cap-dependent translation is impaired, an alternative translation might have a role in the apoptotic process. Therefore, we evaluated if in yeast, the translation of key apoptotic regulators, namely the pro-apoptotic protein Aif1p [41], crucial for the progression of acetic acid-induced apoptosis [41], and the anti-apoptotic protein Bir1p (homologous of mammalian IAP proteins [197], such as XIAP) were translated during acetic acid treatment. Monosomal and polysomal fractions of wild-type cells (Figure 16A) were analyzed by RT-PCR. The analysis of the percentage of *AIF1* mRNA present in each fraction of the polysomal profile revealed that despite of a small increase in the percentage of *AIF1* in the monosomal fraction of treated cells (Figure 16B), there was still a significant amount of *AIF1* mRNA in polysomal fractions upon 15 min (Figure 16B) and 30 min (data not shown) of incubation with acetic acid, when compared to polysomal fractions of untreated cells. The results indicated that *AIF1* mRNA translation is

**Figure 16** - RT-PCR analysis of apoptotic regulators mRNA levels by upon acetic acid treatment. (A) Illustration of the polysomal fractions from which mRNAs were extracted and analysed by RT-PCR (M, monosomal fraction; P1, P2, P3 and P4, polysomal fractions). Analysis of the percentage of (B) *AIF1*, (C) *BIR1*, (D) *TIF4632* and (E) *CLN3* mRNA absolute expression, by RT-PCR and DNA electrophoresis in agarose gel, in each of the polysomal profile fractions of untreated and acetic acid treated cells (195 mM) during 15 min.

occurring despite global translation impairment. As an opposite results almost no *BIR1* mRNA was observed in the polysomal fractions upon 15 (Figure 16C) and 30 min (data not shown) of acetic acid treatment. In fact, after acetic acid treatment, the percentage of *BIR1* mRNA (Figure 16C) was reduced in the polysomal fractions and increased in monosomal fraction, both at 15 (Figure 16C) and 30 min of incubation (data not shown), indicating that upon acetic acid treatment the translation of this apoptotic regulator was reduced. These results were confirmed by the analysis, as a negative control, of the percentage of *CLN3* mRNA in each fraction (Figure 16E). *Cln3* is a G1 cyclin described as unable of being translated by a cap-independent mechanism [234], and as expected the percentage of *CLN3* mRNA in the polysomal fractions was also decreased in cells challenged with acetic acid (Figure 16E). eIF4G (*TIF4632*) was previously shown to be translated by an IRES-mediated cap-independent mechanism being also crucial for the efficient IRES-mediated translation of other mRNAs during nutrient starvation [227]. Therefore, the percentage of *TIF4632* (eIF4G) mRNA was also assessed in an attempt to uncover if during acetic acid treatment, a condition known to induce amino acid starvation [215], and translation impairment, eIF4G was also translated. Results showed that, similar to *AIF1* mRNA, *TIF4632* mRNA levels slightly increased in the monosomal fraction but were strongly present in the polysomal fractions (Figure 16D) proving its ability to be translated during acetic acid treatment and suggesting the activation of an IRES-mediated translation. These results suggest that in yeast, like in mammalian cells, a cap-independent translation mechanism may be mediating the translation of several mRNAs involved in the modulation of the apoptotic process.

## 2.5 DISCUSSION

Over the past few years, the involvement of the translation process in the regulation of apoptosis has emerged as a crucial mechanism both in mammalian and yeast cells [4, 59, 60, 95, 215, 218, 220, 243, 286, 287]. Since translation is the final stage in the course of genetic information flow, regulation at this level leads to a direct response to changes in physiological conditions. During *S. cerevisiae* acetic acid-induced apoptosis, a general amino acid starvation occurs and a translation reduction might allow cells to conserve resources and to initiate a reconfiguration of gene expression. In fact, our results clearly demonstrate a gradual impairment of the translation process during acetic acid treatment. In an early stage, a decrease in the levels of translation initiation factor eIF4A and an increase in the phosphorylation levels of eIF2 $\alpha$  mediated by Gcn2p occur, leading to the inhibition of cap-dependent translation initiation. However, only at later time points a decrease in the levels of translation initiation factor eIF4G and elongation factors eEF1A and eEF2 is observed. In fact, in yeast, the eIF4G, a translation factor known to harbor an IRES in the 5'UTR [227], and eEF1A have been described as crucial factors for an efficient IRES-mediated translation [227, 232]. These data strongly suggest that although cap-dependent translation is impaired during acetic acid treatment, an alternative translation mechanism may be activated, such as the IRES-mediated process. A similar regulation of translation process has been described during oxidative stress induced by H<sub>2</sub>O<sub>2</sub> [220], but an alternative translation mechanism has never been suggested. The alternative cap-independent translation might be important in controlling the translation of proteins with a central role in the stress response to stress of cells struggling to survive and the apoptotic process of cells committed to death. Curiously, Gcn2 kinase appears to be a key mediator of the acetic acid-induced apoptosis, since deletion of *GCN2* gene reverts not only the previously described decrease in eIF4A, eEF1A and eEF2 levels, but also the eIF2 $\alpha$  phosphorylation, leading to unblocked translation and to the abrogation of acetic acid-induced cell death. Besides Gcn2p role in the control of translation initiation, this kinase is also involved in the regulation of other processes, such as cell cycle [247] and autophagy [249]. Investigation of the

contribution of these processes for Gcn2p key participation in the acetic acid-induced apoptosis revealed that cell cycle arrest in G0/G1 phase upon acetic acid treatment [215] is mediated by Gcn2p.

Although we could not detect a marked autophagic response after 200 min of acetic acid treatment in the wild-type strain, a slight increase in the levels of *ATG8* mRNA detected by RT-PCR and Atg8p visualized by epifluorescence microscopy analysis of Atg8p-GFP localization with the cell vacuoles suggest that autophagy might be activated during acetic acid treatment. Furthermore, the pharmacological modulation of the autophagic process revealed that in acetic acid challenged cells autophagy acts as a pro-survival mechanism in response to the acid stress despite the diminished levels of *ATG8* after 200 min of acetic acid treatment. These data made us hypothesize that autophagy might be activated during yeast cells early response to stress decreasing during the course of acetic acid treatment due to the activation of the apoptotic cascade. However, the activation of autophagy during acetic acid treatment appears to be mediated by other autophagy regulators besides Gcn2p. Thus, these studies allowed the elucidation of Gcn2p function during acetic acid-induced apoptosis, showing the critical contribution of this kinase to the inhibition of cap-dependent translation initiation and cell cycle arrest, increasing the knowledge on the acetic acid apoptotic cascade.

In mammalian cells, the control of translation initiation by the apoptosis inducing factor 1 (AIF1), homologous of yeast Aif1p, has been described [76]. Aif1p is a crucial player of yeast acetic acid-induced apoptosis [41]. Thus, a role for this pro-apoptotic protein in translation machinery alterations during acetic acid treatment was addressed through proteomic analysis of *AIF1* deleted cells treated with acetic acid. The proteomic analysis of wild-type and *AIF1* deleted cells showed the same alterations in the levels of translation factors upon acetic acid treatment. A decrease in the levels of translation factors eIF4A, eEF1A and eEF3 in *AIF1* deleted cells was observed both in acetic acid-induced stress (195 mM) and cell death conditions (270 mM) proving that, in yeast, Aif1p is not involved in the control of translation initiation during apoptosis. In fact, it appears that it is the translation process that regulates Aif1p function in apoptosis. Polysomal fractions RT-PCR analysis shows that *AIF1* as well as eIF4G (*TIF4632*) mRNAs are

efficiently translated upon acetic acid treatment despite the observed impairment of cap-dependent translation suggesting the activation of an alternative cap-independent mechanism mediating *AIF1* and eIF4G mRNA translation, during acetic acid treatment.

Altogether, our data demonstrate the importance of translation control during acetic acid treatment at a concentration that induces a stress response in 40% of the cells and commits to death the remaining 60% of the cells upon 200 minutes of treatment. The translation alterations observed in this heterogeneous population strongly suggest that translation control is important both for the cell survival response and the cell death process. Furthermore, this study highlighted some of the translation regulatory mechanisms controlling acetic acid induced apoptosis. The early impairment of cap-dependent translation initiation, mediated by Gcn2p, and the later decrease in the levels of eIF4G, eEF1A and eEF2 strongly suggest the activation of an alternative IRES-mediated cap-independent translation during acetic acid treatment. This cap-independent translation appears to mediate the translation of *AIF1* and eIF4G (*TIF4632*) mRNAs during acetic acid treatment. *AIF1* is a pro-apoptotic factor and its translation during acetic acid treatment is clearly related to the cell death process. However, IRES-mediated translation of eIF4G has been related to nutrient starvation-induced stress conditions [227], therefore its translation during acetic acid treatment might be related with the cellular response to stress.

These results showed an intricate network of regulatory pathways in the course of the apoptotic process induced by acetic acid, thus opening new perspectives for future investigations. In this apoptotic scenario, translation process appears to be an important link for the different pathways.

### 3.1 ABSTRACT

In mammalian cells, translation factors are substrates of caspases during the apoptotic process. In yeast, metacaspase (Yca1p), a caspase-like protease, is required for the execution of apoptosis upon a wide range of stimuli. However, the specific degradome of this protease has not been unraveled so far. In a search for conserved translation factors targeted as substrates by metacaspase, a degradome and deletion analysis were performed using two paradigmatic scenarios of yeast apoptosis, H<sub>2</sub>O<sub>2</sub> and acetic acid. Degradome analysis revealed several spots corresponding to proteins fragments. However, only a small group of individualized spots were identified corresponding to the glycolytic enzyme, the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) [219]. Nitric oxide (NO) signaling was shown to be required for metacaspase specific GAPDH cleavage [219].

In a search for possible mitochondrial substrates, mitochondrial proteomic analysis showed the cleavage and translocation of translation elongation factors 1A (eEF1A) and 2 (eEF2) to mitochondria. Furthermore, a proteinase K assay revealed that eEF1A N-terminal fragments are imported to mitochondrial matrix, performing a putative pro-apoptotic role, upon acetic acid-induced apoptosis [215]. Interaction between eEF1A and Dnm1p [288], a dynamin-related GTPase required for mitochondrial fission [289], has been previously reported [288]. Nevertheless, Dnm1 appears to play no role in the eEF1A mitochondrial localization. eEF1A is a yeast well described bona fide actin binding and bundling protein, and its translocation to mitochondria was correlated with a decrease of its binding to actin leading to alterations in the actin cytoskeleton [290]. Therefore, the role of mammalian eEF1A1 isoform and DRP1, a Dnm1p homolog, in the actin cytoskeleton organization and cell survival was also addressed in HeLa cells during staurosporine-induced apoptosis. These results unravel eEF1A as an important player in cell death process both in yeast and mammalian cells, in a way unrelated to its function in translation. Nevertheless, eEF1A cleavage upon acetic acid treatment proved not to be mediated by metacaspase. Despite that, the analysis of other translation factors levels during acetic acid-induced apoptosis in the absence of metacaspase, suggests a role for this protease in the activation of Gcn2 kinase-mediated phosphorylation of subunit  $\alpha$  of translation initiation factor 2 (eIF2 $\alpha$ ) and

in the downregulation of the translation initiation factor 4A (eIF4A), observed during the apoptotic process. However, to assess if this regulation is mediated by direct interaction of Gcn2p and eIF4A with metacaspase or by interaction with its upstream regulators further studies are required. In conclusion, in this work, we demonstrate eEF1A and eEF2 cleavage and translocation to mitochondria, where they appear to play a role unrelated to translation. Moreover, we highlight GAPDH as a substrate of metacaspase, speculating its possible role in the regulation of translation, and reveal translation initiation factors eIF2 $\alpha$  and eIF4A as downstream targets of the metacaspase cascade, in apoptotic conditions, consolidating the existence of conserved molecular pathways targeted during apoptosis from yeast to mammals.

## 3.2 INTRODUCTION

The apoptotic cascade is orchestrated by different “executioner” caspases which target specific substrates within the cell producing the biochemical and morphological alterations associated to apoptosis. Fragmentation of translation factors by caspases, namely translation initiation factor 2 subunit  $\alpha$  (eIF2 $\alpha$ ), 3 (eIF3), 4B (eIF4B) and 4G (eIF4G) [59, 72, 83], as a mechanism of translational control during the apoptotic process is widely described in mammalian cells [59, 72, 83] [4, 66, 67, 95, 286, 287]. One of the strategies reported is the acquisition of distinct functions, unrelated with the translation process, of translation factors upon the induction of apoptosis. The translation elongation factor 1A (eEF1A) is committed to translation through the delivery of aminoacyl-tRNAs (AA-tRNAs) to ribosomes, but has also been implicated in several other processes, such as, nuclear export of proteins [291], cancer, aging and apoptosis [287, 288, 292-294]. Moreover, eEF1A plays an imperative role, conserved from yeast to mammalian cells, in the control of the actin cytoskeleton organization, by a direct C-terminal interaction with F-actin. A deregulation of eEF1A levels within the cell leads to severe actin cytoskeleton alterations [289, 295-300]. In *Trypanosoma brucei*, this translation factor was even associated to the import of tRNAs to the mitochondria [301, 302]. Nevertheless, the role of eEF1A in tRNA import to mitochondria in yeast and mammalian cells [303-305] was never addressed. In yeast, interaction between eEF1A, codified by *TEF1* and *TEF2* isoforms [306-308], and Dnm1p, a dynamin-related GTPase with a role in mitochondrial fission, has been established [288]. Despite the function of eEF1A isoforms in the translation process, these isoforms appear to acquire divergent functions in other processes, both in yeast and in mammalian cells [287, 309-313].

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is a well-known glycolytic enzyme playing multiple functions and interacting with multiple partners independent of its role in energy metabolism [314-316]. In fact, a role of GAPDH in the repression of specific mammalian cells mRNAs translation, such as angiotensin II type 1 receptor (AT1R) [317] and p53 [134, 318], which was proven to harbor an internal ribosome entry site (IRES) sequence in the mRNA

[119-121], through binding to the 3' untranslated region (3'UTR) of the mRNAs [134, 317] has been suggested. The repression of virus translation by GAPDH, through interaction with IRES present in the virus mRNAs [135-138], has also been reported. The specific cleavage of GAPDH by caspase-1 during apoptosis [139], a process known to require IRES-mediated translation [4, 95, 243], suggests a tight regulation of GAPDH function in the repression of mRNAs translation during apoptosis.

Although in yeast, a member of a family of caspase-like proteases [40], metacaspase (Yca1p), has been reported as an apoptotic executor upon a wide range of either physiological or external stimuli [40, 214], the substrates targeted by this protease are still unknown. Yeast single metacaspase is a type I metacaspase with a prodomain, similar to that of inflammatory and pro-apoptotic initiator caspases [319], that is processed during its activation [40]. Conflicting data exists regarding the ability of yeast metacaspase to cleave typical mammalian caspase substrates [40]. However, yeast metacaspase was shown to cleave P1-Arg and P1-Lys substrates similarly to plant metacaspases [48, 320]. Metacaspases activity was also found to be regulated through S-nitrosation and thus dependent on the endogenous levels of nitric oxide (NO) [210]. Accordingly, during yeast H<sub>2</sub>O<sub>2</sub>-induced apoptotic conditions [189], a cell death process dependent on metacaspase activity [40] and NO generation [211, 212], metacaspase activity and cell death are abolished in the presence of L-NAME, an inhibitor of NO synthesis [211, 212]. In this context, the identification of yeast metacaspase specific substrates mediating translation alterations and of putative new functions performed by translation factors, unrelated to the translation process, during acetic acid treatment is crucial. This information is of utmost importance for the integrated understanding of translation process contribution to the acetic acid-induced apoptosis and to clarify if a conservation of the apoptotic targeted pathways occurs from yeast to mammalian.

### 3.3 MATERIALS AND METHODS

#### Strains, media and treatments

*Saccharomyces cerevisiae* strain BY4742 (*MAT $\alpha$  his3 $\Delta$ 1 leu2 $\Delta$ 0 lys2 $\Delta$ 0 ura3 $\Delta$ 0*) and its isogenic derivatives  $\Delta$ *yca1* and  $\Delta$ *dnm1* (EUROSCARF, Frankfurt, Germany) were used. Strain M198 (*MAT $\alpha$  leu2-3,112 his4-713, met2-1, ura3-52, trp1- $\Delta$ 1  $\Delta$ *tef1::LEU2*) (kindly provided by Prof. Sandbaken), corresponding to  $\Delta$ *tef1* cells previously described in [35], was also used. For construction of the metacaspase-overexpressing strain, *YCA1* was amplified by PCR (primers 5'-ccgggaattcgatgtatccaggtagtgacgt-3' and 5'-ccgggatccctacataataaattgcagatttacgtc-3'), using genomic DNA, isolated from BY4742 strain and cloned into the EcoRI and BamHI sites of pGREG546 (EUROSCARF, Frankfurt, Germany), in order to express a N-terminal GST fusion under the control of a galactose-inducible promoter, generating pGREG546*YCA1*. Strain  $\Delta$ *yca1* was transformed with pGREG546*YCA1*, generating strain *YCA1*<sup>overexp</sup>. Construction of p416 plasmids eEF1A and eEF1A fragments N6C458, N1C146 and N1C177*

were amplified by PCR using the primers described in Table 5, digested and cloned into the BamHI and Sall sites of p416 which displays a galactose-inducible promoter. Wild-type cells were transformed with the plasmids. For construction of

pYX222 plasmids harboring the eEF1A gene or eEF1A N6C177 between a mitochondrial localization sequence (MLS) and a DsRed reporter gene eEF1A gene and N6C177 fragment were amplified by PCR using the primers described in Table 1, digested with BamHI, and cloned into pYX222 vector between the N-terminal MLS and the C-terminal DsRed (kindly provided by Dr. Stephan Jacobs). *Δtef1* cells were transformed with the plasmids.

Wild-type cells expressing the p416 plasmids with the eEF1A fragments were grown until exponential growth phase ( $OD_{640nm}=0.5$ ) on synthetic complete (SC) medium containing glucose (2%, w/v), yeast nitrogen base (0.17%, w/v, Difco), 300 mg/L of L-leucine, 50 mg/L of L-histidine and 50 mg/L of L-lysine. Cells were washed, resuspended in SC medium containing galactose (2%, w/v) and incubated at 26°C with stirring (150 r.p.m.) to induce the eEF1A total protein and fragments expression. After 16 hours,  $10^8$  cells/mL were harvested and resuspended in fresh SC medium with galactose (2%, w/v) (pH 3.0), treated with 210 or 225 mM of acetic acid and incubated for 200 min at 26°C with stirring (150 r.p.m.).

For  $H_2O_2$  treatment, yeast cells were grown until the early stationary growth phase in liquid YPD medium containing glucose (2%, w/v), yeast extract (0.5%, w/v) and peptone (1%, w/v), harvested and resuspended ( $10^7$  cells/mL) in fresh YPD medium followed by the addition of 0.5, 1, 1.5 and 2 mM  $H_2O_2$  and incubation for 200 min at 26°C with stirring (150 r.p.m.) in the dark, as previously described [211]. For acetic acid treatment, *S. cerevisiae* cells were grown until the middle exponential phase in liquid YPD medium, harvested, resuspended in fresh medium (pH 3.0) and incubated at 26°C for 1h. Then cells were resuspended ( $10^8$  cells/mL) in fresh medium (pH 3.0) followed by the addition of 180, 195, 210 or 225 mM of acetic acid and incubation during 0, 15, 30, 60, 120 and 200 min at 26°C with stirring (150 r.p.m.). After  $H_2O_2$  or acetic acid treatment, approximately 300 cells were spread on YPD agar plates and viability was determined by counting colony forming units after 2 days of incubation at 26°C [199]. Cells were also harvested for protein extraction and immunoblot analysis as described below.

HeLa cells were cultured in DMEM medium (Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum (FBS), 1% glutamax, and 1% antibiotics mixture (Invitrogen) and grown at 37°C in a 5% CO<sub>2</sub> humidified chamber. eEF1A1 (NM\_001402.5), eEF1A2 (NM\_001958.2), and DNMT1 (NM\_005690.3) RNAi depletions were achieved using a pool of small interfering siRNAs (siRNAs) generated from nonconserved sequences (nucleotides 1383-2519, 327-1334, and 348-1757 from the start codon, respectively) with the BLOCK-iT Dicer RNAi kit accordingly to the manufacturer's instructions (Invitrogen). Cells (10<sup>5</sup> cells/well) were plated in DMEM medium with 5% FBS and without antibiotics, on six-well plates (Nunc, Naperville, IL) containing poly-L-lysine-coated glass coverslips. Two hours later, cells were transfected with siRNA-oligofectamine complexes prepared in Opti-MEM I medium (Invitrogen) according to the manufacturer's instructions and analyzed 24 or 48 h after transfection. Mock transfections were used as control. Afterwards, cells were treated with staurosporine for 18h (0.1 µM, Sigma, St. Louis, MO), and cell viability using the CellTiter-Blue® Cell Viability Assay (Promega, Madison, USA), immunofluorescence of eEF1A and actin, and apoptosis detection by TUNEL assay were assessed, as described below.

### **Metacaspase overexpression and activation**

Strain *YCA1*<sup>overexp</sup> was grown until exponential growth phase (OD<sub>640nm</sub>=0.5) on synthetic complete (SC) medium containing glucose (2%, w/v), yeast nitrogen base (0.17%, w/v, Difco), 300 mg/L of L-leucine, 50 mg/L of L-histidine and 50 mg/L of L-lysine. Cells were washed, resuspended in SC medium containing galactose (2%, w/v) and incubated at 26°C with stirring (150 r.p.m.) to induce metacaspase overexpression. After 16 hours, 10<sup>7</sup> cells/mL were harvested and resuspended in fresh SC medium with galactose (2%, w/v), and metacaspase was activated by the addition of 2 mM of H<sub>2</sub>O<sub>2</sub> [40] and incubation for 200 min at 26°C with stirring (150 r.p.m.).

## Preparation of protein extracts

For total protein extracts, untreated, H<sub>2</sub>O<sub>2</sub>- and acetic acid-treated cells were collected and disrupted using glass beads in lysis buffer [1% v/v Triton X-100, 120 mM NaCl, 50 mM Tris-HCl pH 7.4, 2 mM EDTA, 10% v/v Glycerol, 1 mM PMSF and Complete Mini protease inhibitor cocktail (Roche, Mannheim, Germany)] as described in [211, 215]. For mitochondrial protein extracts, yeast cells were harvested and cell wall was digested with zymolyase buffer [2 M Sorbitol-D, Phosphate buffer 1 M (pH 7.5), Zymolyase 20.000 U, 125 mM  $\beta$ -mercaptoethanol, 0.5 M EDTA] at 30°C for 1 hour. Protoplasts were disrupted with lysis buffer [Sorbitol-D 0.5 M, Tris 20 mM, EDTA 1 mM, and 2.85 mM phenylmethanesulphonyl fluoride (PMSF)] using a Potter homogenizator. Mitochondria extracts were separated, washed by high speed centrifugation at 12000 r.p.m. for 15 min at 4°C (Beckman Coulter, JA-25.50 Rotor) and resuspended in sorbitol buffer [0.5 Sorbitol-D, 5 mM EDTA, 50 mM Tris]. HeLa cells were collected by centrifugation and disrupted using RIPA buffer [50 mM Tris-HCl pH 7.6, 150 mM NaCl, 1% NP-40, 1% Na-deoxycholate, 0.1% SDS]. Protein concentration was determined by Bradford method [321] and protein aliquots of yeast total extracts (1 mg, 40  $\mu$ g), yeast mitochondrial extracts (600  $\mu$ g, 100  $\mu$ g and 40  $\mu$ g) and HeLa cells total extracts (40  $\mu$ g) were stored at -20°C.

## Digestome analysis

Digestome analysis was performed according to the methodology previously described in [322], with adaptations. Four hundred micrograms of total protein extracts obtained from untreated wild-type yeast cells or HeLa cells were resolved by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) 12% (first dimension). After migration, the lanes were excised and treated as described in [322], soaked in digestion buffer [50 mM Tris-HCl, 150 mM NaCl and 10 mM DTT] with 5 mg of either active metacaspase-enriched extracts (obtained from H<sub>2</sub>O<sub>2</sub>-treated YCA1<sup>overexp</sup> cells) or inactive metacaspase-enriched extracts (obtained from H<sub>2</sub>O<sub>2</sub>-treated  $\Delta yca1$  or untreated YCA1<sup>overexp</sup> cells), incubated overnight at 37°C, washed with ultrapure water and incubated in loading buffer [50 mM Tris-HCl (pH 6.8), 2% SDS, 0.1% bromophenol blue, 10% glycerol,

2.5%  $\beta$ -mercaptoethanol] for 10 min at 95°C. After cooling, lanes were subjected to a second dimension SDS-PAGE. Proteins in the gels were immunoblotted as described below or stained using Colloidal Blue Staining Kit (Invitrogen) for mass spectrometry identification.

## **2-DE**

Three independent samples from mitochondrial extract were used to verify the reproducibility for each of the two conditions (control and 195 mM acetic acid-treated cells) and each sample separated within four 2-D gels. For 2-DE the protein pellet was resuspended in urea buffer (8 M urea, 2 M thiourea, 1% [w/v] CHAPS, 20 mM DTT, 0.8% [v/v] carrier ampholytes and Complete Mini protease inhibitor cocktail). The protein separation was done as previously described [164]. Briefly, the protein solution was adjusted with urea buffer to a final volume of 350  $\mu$ L and in-gel rehydration was performed over night. Isoelectric focusing (IEF) was carried out in IPG strips (pH 3–10, non linear, 18 cm; GE Healthcare, Uppsala, Sweden) with the Multiphor II system (GE Healthcare) under paraffin oil for 55 kVh. SDS-PAGE was done overnight in polyacrylamide gels (12.5% T, 2.6% C) with the Ettan DALT II system (GE Healthcare) at 1-2 W per gel and at 12°C. The gels were silver stained and analyzed with the 2-DE image analysis software Melanie 3.0 (GeneBio, Geneva, Switzerland). The apparent isoelectric points (pI) and molecular masses (Mr) of the proteins were calculated with Melanie 3.0 (GeneBio) using identified proteins with known parameters as a reference. An expression change was considered significant if the intensity of the corresponding single spot differed reproducibly more than two-fold and was reproducible for all three experiments.

## **Identification of altered proteins by mass spectrometry**

To identify low abundant proteins, the spots were excised from 2-D gels separated with 600  $\mu$ g of protein, in-gel digested, and identified from the peptide fingerprints as described elsewhere [251]. Proteins were identified with the ProFound database, version 2005.02.14 (<http://prowl.rockefeller.edu/prowl/cgi/profound.exe>) using the following parameters: 20 ppm; 1 missed cut; MH+;

+C2H2O2@C (Complete), +O@M (Partial). The identification of a protein was accepted if the peptides (mass tolerance 20 ppm) covered at least 30% of the complete sequence. Sequence coverage below 20% was only accepted if at least three main peaks of the mass spectrum matched with the sequence and the number of weak-intensity peaks was clearly reduced. If the protein spot was detected at a lower molecular mass than expected, which indicates processing or fragmentation, the spot-specific peptides in the mass spectrum were also analyzed to confirm which parts of the corresponding protein sequence matched with these peptides. If the mass spectrum of the spot lacked peptides observed for the complete protein it was indicated as a protein fragment. Therefore, both the spot position observed by 2-DE and the specific peptides in the corresponding mass spectrum were analyzed to indicate a putative protein fragment.

### **Proteinase k assay**

Three aliquots of 100  $\mu$ g mitochondrial protein extracts of each sample were centrifuged at 13000 r.p.m. for 10 min at 4°C. Supernatants were discarded and two aliquots pellets (1 and 2) of each sample were resuspended in 500  $\mu$ L of HS buffer [0.6 M Sorbitol-D, 20 mM HEPES-KOH, pH 7.4] and the other (3) was resuspended in H buffer [20 mM HEPES-KOH, pH 7.4]. 5  $\mu$ L of dH<sub>2</sub>O was added to pellet 1 and 5  $\mu$ L of 10 mg/mL proteinase K to pellets 2 and 3. Mitochondrial extracts were incubated for 25 min on ice and 5  $\mu$ L of 0.2 M PMSF was added to each sample followed by 5 min incubation on ice. Samples were centrifuged at 13000 r.p.m. for 10 min at 4°C, pellets were resuspended in HS buffer, precipitated overnight in acetone, and centrifuged at 13000 r.p.m. for 30 min at 4°C. Supernatants were discarded, pellets were dried, resuspended in 30  $\mu$ L of Laemmli buffer (BioRad) and immunoblotted as described in below.

### **Immunoprecipitation**

Anti-actin antibody was added to 1 mg of total protein extracts from untreated and acetic acid treated yeast cells in a total volume of 500  $\mu$ L and incubated for 4h at 4°C on a shaker. Afterwards, 20  $\mu$ L of washed protein A/G agarose beads (Pierce) were added to each sample and incubated overnight at 4°C

on a shaker. Agarose beads were collected by centrifugation (3000 rpm, 1min, 4°C), washed twice with 1 mL ice-cold lysis buffer [1% v/v Triton X-100, 120 mM NaCl, 50 mM Tris-HCl pH 7.4, 2 mM EDTA, 10% v/v Glycerol, 1 mM PMSF and Complete Mini protease inhibitor cocktail (Roche, Mannheim, Germany)] and with 1mL ice-cold wash buffer [0.1% v/v Triton X-100, 120 mM NaCl, 50 mM Tris-HCl pH 7.4, 2 mM EDTA and 10% v/v Glycerol]. Afterwards, agarose beads were eluted in 30  $\mu$ L of Laemmli buffer (BioRad), boiled for 5 min to dissociate the immunocomplexes from the beads and collected by centrifugation (10000 r.p.m., 1min). The supernatant fraction was immunoblotted as described in below.

### **Immunoblotting**

Yeast total and mitochondrial protein extracts, mitochondrial extracts from proteinase K assay, supernatants from actin immunoprecipitation and HeLa cells total extracts were resolved on a 12% SDS-PAGE gel and transferred to a nitrocellulose membrane (Amersham) over 90 min at 100 V. Total protein extracts of the digestome analysis were probed with a monoclonal mouse anti-GAPDH (MAB474, Chemicon) as described [211] and a polyclonal rabbit anti-S-nitroso-cysteine (CSNO) (N5411, Sigma-Aldrich) at a dilution of 1:500. Total protein extracts of H<sub>2</sub>O<sub>2</sub>- and acetic acid-treated cells were probed with polyclonal rabbit Ser51 phosphorylated eIF2 $\alpha$  (Sui2) antibody (1:2000, Upstate), polyclonal rabbit anti-eIF2 $\alpha$  (1:2000, Cell Signaling Technology), polyclonal rat anti-eIF4G (Tif4631/Tif4632p) (1:1000, kindly provided by Michael Altmann), polyclonal rabbit anti-eEF2 (Eft1/2p) (1:15000), polyclonal rabbit anti-eEF1A (Tef1/2p) (1:15000, both antibodies were kindly supplied by Prof. T.G. Kinzy), polyclonal rabbit anti-eIF4A (Tif1/2p) (1:15000, kindly supplied by Prof. M. Montero-Lomelí), polyclonal goat anti-actin (1:5000, kindly provided by Campbell Gourlay), monoclonal rabbit anti-aconitase antibody (1:1500, kindly provided by Lill, R.) and monoclonal mouse anti-porin antibody (1:5000, MAB474, Chemicon). Membranes of HeLa cells protein extracts were probed with polyclonal mouse anti-eEF1A (1:750, Santa Cruz Biotechnology, Inc) and polyclonal goat anti-actin (1:300, Santa Cruz Biotechnology, Inc). Horseradish peroxidase (HRP)-conjugated anti-rabbit, anti-rat, anti-goat and anti-mouse IgG secondary antibodies (Cell Signaling

Technology) were used, at a dilution of 1:5000 and detected using an enhanced chemiluminescence's kit (Pierce).

### **Assessment of intracellular reactive oxygen species (ROS)**

Free intracellular ROS were detected with dihydrorhodamine 123 (DHR123) (Molecular Probes, Eugene, OR, USA). DHR123 was added from a 1 mg/mL stock solution in ethanol, to  $5 \times 10^6$  cells/mL suspended in PBS, reaching a final concentration of 15  $\mu\text{g/mL}$ . Cells were incubated for 90 min at 30°C in the dark, washed in PBS and analyzed by flow cytometry. Flow cytometric assays were performed on a BD LSR II™ (Becton Dickinson, NJ, USA) using BD FACSDiva Software 6.0 (Becton Dickinson, NJ, USA). Twenty thousand cells per sample were analyzed using the FlowJo software (Tree Star, Ashland, OR, USA). Data express the percentage of DHR123-positive cells compared to the total number of counted cells.

### **TUNEL assay**

DNA strand breaks were assessed by Terminal Deoxynucleotidyl Transferase-mediated dUTP Nick End Labeling (TUNEL) assay with the In situ Cell Death Detection Kit, POD (Roche Applied Science, Indianapolis, IN). Yeast cells were initially fixed with 3.7% formaldehyde followed by digestion of the cell walls with lyticase. After preparation of cytopins, the slides were rinsed with PBS, incubated in permeabilization solution (0.1%, v/v, Triton X-100 and 0.1%, w/v, sodium citrate) for 3 min on ice, rinsed twice with PBS, and incubated with 10  $\mu\text{L}$  of TUNEL reaction mixture (terminal deoxynucleotidyl transferase and FITC-dUTP) for 60 min at 37°C. Finally, the slides were rinsed three times with PBS and incubated with 40  $\mu\text{L}$  of PI/RNase solution (PI 50  $\mu\text{g/mL}$  and RNase 12.5  $\mu\text{g/mL}$ ) in Tris buffer (10 mM, pH 7.0) for 20 min at 37°C in the dark. Coverslip was mounted with a drop of anti-fading agent Vectashield (Molecular Probes, Eugene, OR). HeLa cells DNA strand breaks were assessed according to the manufacturer's instructions. Cells were visualized with an Olympus PlanApo 60X/oil objective, with a numerical aperture of 1.42. For quantification of TUNEL-positive cells, at least

400 cells from three independent assays were counted. Data express the percentage of TUNEL-positive cells compared to the total number of counted cells.

### **Immunofluorescence**

HeLa cells were fixed for 20 min in freshly prepared 2% paraformaldehyde (Sigma) in phosphate-buffered saline (PBS), permeabilized with 0.5% Triton X-100 in PBS for 5 min, washed in PBS and blocked with 10% FBS. Primary antibodies were used as follows: mouse anti-eEF1A (1:250, Cruz Biotechnology, Inc) and goat anti-actin (1:300, Cruz Biotechnology, Inc). Alexa Fluor 488, and 568 conjugated secondary antibodies were used at 1:1500 (Molecular Probes, Eugene, OR) and DNA was stained using 4,6-di-amino-2-phenyl-indole dihydrochloride (DAPI) (Sigma). Most images were acquired as Z-stacks with 0.2–0.3- $\mu$ m spacing using a 60x 1.42 NA objective on an Olympus FluoView FV1000 confocal microscope.

### **Statistical analysis**

Arithmetic means of free intracellular ROS, TUNEL staining and cell survival rates are presented with standard deviation with a 95% confidence value. Statistical analysis was carried out using independent samples *t*-test analysis. A *p*-value <0.05 was assumed to denote a significant difference.

## 3.4 RESULTS

To disclose if translation factors are specific substrates of yeast metacaspase in yeast apoptotic scenarios associated with an impairment of translation process, namely  $H_2O_2$ - [220] and acetic acid-induced apoptosis (chapter 2), a digestome analysis [322] and a mutagenesis analysis of *YCA1* deleted cells were performed.

### 3.4.1 Metacaspase-mediated alterations during $H_2O_2$ -induced apoptosis

#### **3.4.1.1 Digestome analysis revealed GAPDH as a cleavage target of metacaspase**

With the aim of disclosing translation factors as substrates of yeast metacaspase during  $H_2O_2$ -induced apoptosis a digestome analysis was performed. Although digestome analysis, an in vitro assay, does not mimic cellular physiological conditions, it represents a starting point in the search for putative specific substrates of proteases. In a first dimension SDS-PAGE, total protein extracts from untreated wild-type yeast cells were resolved. Upon protein separation, gel lanes were excised and incubated with active metacaspase-enriched extracts obtained from *YCA1*<sup>overexp</sup> cells undergoing apoptosis induced by  $H_2O_2$  treatment (a condition known to induce metacaspase activation [40]). After incubation, gel lanes were mounted on a second SDS-PAGE gel and proteins resolved a second time by molecular weight. Digestome analysis of total protein extracts revealed numerous spots below the diagonal, corresponding to putative protein fragments of metacaspase substrates cleaved during the incubation of the gel lane with active metacaspase-enriched extracts (Figure 17A) [219]. However, by mass spectrometry, we were only able to identify three of these spots (Figure 17A, spot 1, 2 and 3), corresponding to peptide fragments of the isoforms 2 or 3 (Tdh2p/Tdh3p), but not of the isoform 1 (Tdh1p), of the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Figure 17B). Immunoblot of the digestome analysis using active metacaspase-enriched extracts with an anti-

**Figure 18** – Digestome analysis of protein extracts from wild-type untreated cells incubated with protein extracts from (A)  $H_2O_2$ -treated *YCA1*<sup>overexp</sup> cells; (B) untreated *YCA1*<sup>overexp</sup> cells and (C)  $H_2O_2$ -treated  $\Delta yca1$  cells. Immunoblot analyses with a monoclonal anti-GAPDH antibody revealed spots 4, 5 and 6. Data are representative of at least three independent experiments. (D) Immunoblot analysis of diagonal gel represented in (A) with anti-S-nitroso-cysteine (CSNO) antibody.

activity. However, two other spots (spots 4 and 5) were detected in the digestome analysis under active metacaspase conditions (Figure 18A) and were not generated when active metacaspase was absent. These data suggest that GAPDH is cleaved

by metacaspase and that specific cleavage products only occur when metacaspase is active.

Our previous data have demonstrated that upon  $H_2O_2$ -induced apoptosis, yeast cells are able to synthesize nitric oxide (NO) leading to the S-nitrosation of GAPDH [211]. Therefore, we questioned if the metacaspase specific GAPDH cleavage and NO signalling are correlated. Immunoblot with an anti-CSNO antibody in the same experimental conditions revealed that the three GAPDH fragments were nitrosated (Figure 18D). Therefore, these results suggest the occurrence of an NO signalling for metacaspase-mediated GAPDH cleavage and demonstrate that the role of metacaspase in yeast  $H_2O_2$ -induced apoptosis involves the cleavage of the glycolytic enzyme GAPDH.

Since in mammalian cells the cleavage of GAPDH by caspase-1 has been described [139] and GAPDH sequence is highly conserved among species, we

**Figure 19** - Mammalian GAPDH is a cleavage target of metacaspase-enriched protein extracts. Coomassie-stained diagonal gels of total protein extracts from untreated HeLa cells incubated with protein extracts from (A)  $H_2O_2$ -treated *YCA1*<sup>overexp</sup> cells; (B) untreated *YCA1*<sup>overexp</sup> cells and (C)  $H_2O_2$ -treated  $\Delta yca1$  cells, and respective immunoblot analysis with a monoclonal anti-GAPDH antibody. Data are representative of at least three independent experiments.

decided to evaluate a functional conservation of GAPDH cleavage sequences from yeast to mammalian cells. Digestome analysis of HeLa cells total protein extracts incubated with active metacaspase-enriched extracts was performed. As expected, metacaspase was able to cleave mammalian GAPDH (Figure 19A). Immunoblot analysis of the diagonal gels revealed two GAPDH spots immediately below the

diagonal (Figure 19A) although these fragments were distinct from the ones produced by incubation with yeast protein extracts, showing that these proteases have distinct cleavage target sites. Furthermore, diagonal gels of HeLa cells total protein extracts after incubation with extracts from untreated *YCA1*<sup>overexp</sup> cells or H<sub>2</sub>O<sub>2</sub>-treated *Δyca1* cells showed that the absence of metacaspase activity (Figure 19B, 19C) resulted in the lack of GAPDH fragments below the full-length GAPDH protein, indicating that mammalian GAPDH specific cleavage products only occur when metacaspase is active. Our results indicate that yeast metacaspase recognizes target sequences distinct from the ones recognized by caspases of higher eukaryotes corroborating previous results that attributed to metacaspase an arginine/lysine-specific endopeptidase activity in contrast to the cysteine-aspartic proteases of caspases [320]. Altogether, these results show that although metacaspases have a proteolytic activity distinct from caspases, their targeted molecular pathways upon an apoptotic stimulus display similarities and during apoptotic cell death both of them degrade metabolic enzymes. Despite these results, we were unable to address a role for metacaspase in the cleavage of translation factors, as described in mammalian cells, since we could not identify the other numerous spots observed below the diagonal in the digestome analysis. Nevertheless, in mammalian cells a regulation of internal ribosome entry site (IRES) mediated cap-independent translation of virus and mammalian mRNAs [135-138] and of mRNA stability by GAPDH [323] has been addressed. The conserved degradation of GAPDH in the course of the apoptotic cascade might be a regulatory mechanism for the activation of an IRES-mediated translation upon the apoptotic stimulus from yeast to mammalian cells.

#### **3.4.1.2 In vivo metacaspase cleavage of GAPDH during H<sub>2</sub>O<sub>2</sub>-induced apoptosis**

Several proteins shown to be specifically cleaved by in vitro methodologies, such as the digestome analysis, proved later not to be substrates of the caspases under in vivo apoptotic conditions. Thus, metacaspase specific GAPDH fragmentation was evaluated by immunoblot analysis of GAPDH levels, in total

**Figure 20** - GAPDH specific cleavage by metacaspase during H<sub>2</sub>O<sub>2</sub>-induced apoptosis. (A) Immunoblot analysis of GAPDH and actin protein levels in 40  $\mu$ g of total protein extracts of H<sub>2</sub>O<sub>2</sub>-treated and untreated wild-type and  $\Delta yca1$  cells. (B) Comparison of the survival rate of wild-type and  $\Delta yca1$  cells upon H<sub>2</sub>O<sub>2</sub> treatment. (C) Percentage of wild-type and  $\Delta yca1$  cells exhibiting high levels of intracellular ROS detected by FACS measurements of the dihydrorhodamine 123 fluorescence. (D) Percentage of wild-type and  $\Delta yca1$  cells displaying TUNEL positive phenotype. (E) Epifluorescence and bright field micrographs of untreated and H<sub>2</sub>O<sub>2</sub>-treated wild-type and  $\Delta yca1$  cells displaying TUNEL reaction to visualize double-strand DNA breaks. Cells were co-stained with propidium iodide in order to facilitate nuclei visualization. Bar, 5  $\mu$ m.

protein extracts from wild-type and  $\Delta yca1$  cells challenged with  $H_2O_2$  (Figure 20A). As expected,  $H_2O_2$  (concentrations ranging from 0.5 mM to 2 mM) induced apoptotic cell death of wild-type cells (Figure 20B) as revealed by the high levels of reactive oxygen species (ROS) (Figure 20C) and the increasing percentage of cells displaying TUNEL positive phenotype (Figure 20D, 20E). In contrast,  $\Delta yca1$  cells were more resistant to  $H_2O_2$  and thus had increased survival (Figure 20B), TUNEL negative phenotype (Figure 20D, 20E) and lower percentage of cells with high ROS levels (Figure 20C). Moreover, apoptotic cell death of wild-type cells was accompanied by a clear reduction of the GAPDH levels that was not observed in  $\Delta yca1$  cells (Figure 20A), suggesting the requirement of metacaspase for the occurrence of fragmentation of this protein in vivo. Simultaneously, it was possible to detect a GAPDH fragment with lower molecular weight (15kDa) (Figure 20A) compatible with one of the fragments observed by digestome analysis (Figure 20A). The absence of other fragments in the immunoblot analysis, as observed by in vitro digestome assay, suggests that the peptides liberated from the precursor protein, can be further processed, resulting in fragments that are released or degraded.

These results suggest that GAPDH is a specific target of metacaspase during  $H_2O_2$ -induced apoptosis. As demonstrated in mammalian cells [119, 134, 139], the fragmentation of GAPDH during apoptosis might be part of a mechanism of derepression/activation of an alternative cap-independent translation of specific mRNAs with a role in the yeast apoptotic process.

Altogether these data reinforce a link between translation control, metabolism and cell death. However, the role of metacaspase in translation machinery alterations during cell death remains elusive.

### **3.4.2 Metacaspase-mediated alterations during acetic acid-induced apoptosis**

Since digestome analysis was unable to reveal metacaspase substrates related to the translation machinery, a different approach was followed. As opposed to the incubation of protein extracts with metacaspase, we analysed the

effect of the deletion of *YCA1* in the levels of translation factors affected during the acetic acid-induced apoptosis.

### **3.4.2.1 eEF1A as a modulator of cell death**

#### **eEF1A N-terminal metacaspase-independent fragmentation and re-localization to mitochondrial matrix upon acetic acid-induced apoptosis**

In mammalian cells, the target of mitochondria by caspases has been described as part of the apoptotic cascade [322]. To identify potential metacaspase substrates in mitochondria during acetic acid-induced apoptosis, an apoptotic scenario in which mitochondria plays a prominent role [39, 41, 199-201, 324-328], a proteomic analysis, combined with mass spectrometry, of purified mitochondrial extracts from untreated and acetic acid treated cells was performed, showing that two spots corresponding to fragments of the translation elongation factor eEF1A (Tef1p/Tef2p) were present in mitochondria, upon acetic acid treatment (Figure 21A) [290]. These two eEF1A fragments were composed by the N-terminal sequences of the protein from amino acids 6-177 (Figure 21B, amino acid sequence highlighted at orange) and amino acids 6-146 (Figure 21B, amino acid sequence highlighted at orange and green), with a molecular weight of about 19 kDa [290]. To further validate the proteomic analysis eEF1A levels and cellular localization were assessed. Upon acetic acid treatment a decrease in the levels of eEF1A in cytoplasm was observed together with a re-localization of the total protein and eEF1A fragments (with molecular weight of about 19 kDa and 31 kDa) to mitochondria (Figure 21C). Moreover, to elucidate if the eEF1A fragments detected in the mitochondria upon the apoptotic stimulus were only interacting with mitochondria outer membrane or were able of enter the mitochondrial matrix, a proteinase K assay was performed. Mitochondrial extracts of untreated and acetic acid-treated cells were incubated with proteinase K in the presence or absence of sorbitol (osmotic protector of the mitochondrial membrane integrity). The digestion of the proteins interacting with the outer membrane was assessed through the incubation with proteinase K and sorbitol. Proteins of the outer membrane and intermembrane space were digested through the incubation with proteinase K in the absence of sorbitol. This assay revealed that upon the induction of apoptosis by

**Figure 21** - Re-localization of eEF1A N-terminal fragments to mitochondria during acetic acid-induced apoptosis. (A) Comparison of protein levels in purified mitochondrial extracts of untreated and acetic acid-treated wild-type *S. cerevisiae* cells. Selected two-dimensional gel regions are shown enlarged. Putative protein fragments are marked with an asterisk. Arrows indicate the respective spots. (B) Peptide fingerprints of the two eEF1A fragments corresponding amino acids 5-146 and 6-177 to N-terminal sequences as identified in 2D gel electrophoresis of mitochondrial extracts from acetic acid treated cells. (C) Immunoblot analysis of eEF1A levels in cytoplasmic and mitochondrial extracts of untreated and acetic acid treated wild-type cells. (D) Immunoblot analysis of eEF1A levels after proteinase K assay of mitochondrial extracts from untreated and acetic acid treated cells.

acetic acid, an eEF1A fragment of 30 kDa and total eEF1A protein interact with the outer surface of the mitochondria being immediately removed after digestion with proteinase K in the presence of sorbitol (Figure 21D). However, the eEF1A N-

terminal fragment of 19kDa was detected in the mitochondrial matrix even after the incubation of mitochondrial protein extracts with proteinase K without sorbitol (Figure 21D). The fact that eEF1A was fragmented during acetic acid-induced apoptosis, but was not degraded, being re-localized to the mitochondria raised the hypothesis that beyond its role in translation and the other described functions, eEF1A plays a role in acetic acid-induced apoptosis. Despite this fact, immunoblot

**Figure 22** – eEF1A fragmentation during acetic acid treatment is independent of yeast metacaspase. Immunoblot analysis of eEF1A expression in cytoplasmic and mitochondrial extracts of untreated and acetic acid treated (195 mM)  $\Delta yca1$  cells.

analysis of eEF1A levels in cytoplasmic and mitochondrial extracts of *YCA1* deleted cells showed that eEF1A cleavage upon the acetic acid stimulus was not mediated by metacaspase (Figure 22). Although an interaction between these two proteins has been described [209], eEF1A fragmentation and re-localization to mitochondria still occurs in *YCA1* disrupted cells (Figure 22).

Yeast eEF1A, as well as that of other organisms, is a bona fide actin binding and bundling protein [289, 295-299] with a crucial role in the regulation of actin cytoskeleton organization. Therefore, we addressed whether acetic acid treatment affects the eEF1A binding to actin and the possible implications to the actin cytoskeleton organization. Immunoprecipitation of actin from total protein extracts of acetic acid treated cells followed by immunoblot of eEF1A levels revealed that during acetic acid treatment the affinity of eEF1A to actin was diminished, and this

decrease was dependent on the acetic acid concentration (Figure 23A). The interaction of mitochondria with cytoskeleton elements regulating mitochondrial dynamics, namely mitochondria fusion and fission, has been described both in yeast and mammalian cells [329-331]. In fact, actin and Tef1p, but not Tef2p,

**Figure 23** - Fragmentation and translocation of eEF1A to mitochondria reduces its affinity to actin and is independent of mitochondria dynamics. (A) Immunoprecipitation of actin from total protein extracts of untreated and acetic acid treated cells, followed by immunoblot analysis of eEF1A levels and binding to actin. (B) Immunoblot analysis of eEF1A levels in cytoplasmic and mitochondrial extracts of untreated and acetic acid treated  $\Delta yca1$  cells.

interaction with the Dynamin-related GTPase, Dnm1p, involved in mitochondrial fission, has been previously shown [332]. Although Tef1p interacts with several mitochondrial proteins, the interaction with Dnm1p might be of importance for the execution of the apoptotic process, as Dnm1p has previously been linked to the promotion of mitochondria fragmentation/degradation and cell death upon acetic acid-induced apoptosis in yeast [200, 333]. Our results showed that during acetic acid treatment, eEF1A binding to actin decreased (Figure 23A) and eEF1A N-terminal fragments re-localized to mitochondrial matrix (Figure 21). Thus, we decided to evaluate the relevance of Dnm1p on the translocation of eEF1A fragments to mitochondria. With this purpose, we observed the levels of the eEF1A in cytoplasmic and mitochondrial extracts of untreated and acetic acid treated  $\Delta dnm1$  cells. Immunoblot results exhibited the eEF1A fragments in mitochondria

extracts of *DNM1* deleted cells upon acetic acid-induced apoptosis (Figure 23B) excluding the possibility of the Dnm1p-mediated translocation of eEF1A to mitochondria. Nevertheless, Dnm1p is not the only regulator of the mitochondria fission/fusion process during acetic acid-induced apoptosis [200] and other proteins could be interacting with eEF1A, regulating this process.

A second mitochondrial proteomic analysis was performed under the same apoptotic conditions. This analysis revealed a new spot in mitochondria extracts upon acetic acid treatment, corresponding to the translation elongation factor 2 (eEF2/Eft1/2p) (Figure 24). Nevertheless, a thorough analysis of the function of this protein in mitochondria during acetic acid treatment and of a putative correlation with the eEF1A fragments in this process should be performed.

**Figure 24** – Translocation of eEF2 fragment to mitochondria during acetic acid-induced apoptosis. Comparison of protein levels in purified mitochondrial extracts of untreated and acetic acid-treated (195 mM) wild-type *S. cerevisiae* cells. Selected regions of the two-dimensional gel are shown. Arrows indicate the respective spots.

These results suggest that upon acetic acid treatment the apoptotic cascade is activated, and after 120 min of incubation (Figure 10A) eEF1A is cleaved by a caspase-independent pathway and N-terminal fragments are re-localized to the mitochondrial matrix. The presence of eEF1A N-terminal fragments in mitochondria matrix during the apoptotic process allows us to hypothesize the involvement of eEF1A fragments in the mitochondrial apoptotic cascade. The fact that both eEF1A and eEF2 are found in mitochondria at later time points of the acetic acid treatment strongly suggest that this translocation and the function performed by these fragments in the mitochondria are related with the progression of the apoptotic process. Since *in silico* analysis suggests that the N-terminal fragments of eEF1A, re-localized to the mitochondrial matrix, are GTP-binding domains involved

in the delivery of the aminoacyl-tRNAs to ribosomes and eEF2 is involved in ribosomal translocation during protein synthesis [334], their re-localization to mitochondria might be a signalling for this translation factors participation in the translation of mitochondrial mRNAs with a role in apoptosis.

Moreover, given that eEF1A is an inhibitor of Gcn2p [294, 335], and this kinase plays a crucial role in the regulation of translation initiation during the acetic acid-induced apoptosis (Figure 10A, 11B), the cleavage of eEF1A might be a cellular mechanism to impair this inhibition.

### **The eEF1A N-terminal fragments act as pro-apoptotic molecules upon acetic acid treatment**

Although the previous results ruled out eEF1A as a substrate of metacaspase during the acetic acid-induced apoptosis, we cannot reject the hypothesis that eEF1A N-terminal fragments are players in the apoptotic cascade. To understand the role of eEF1A N-terminal fragments in mitochondria during acetic acid-induced apoptosis, p416 plasmids harbouring eEF1A full gene and eEF1A truncated in N6C458, N1C146 or N1C177 were transformed in wild-type cells. Higher concentrations of acetic acid were used in order to achieve about 50% (210 mM) and 35% (225 mM) of cell death in the wild-type cells harbouring the empty plasmid vector (Figure 25). The expression of the eEF1A total protein (N1C458) did not affect the resistance of wild-type cells to acetic acid. However, expression of eEF1A protein truncated in the first 5 amino acids (N6C458) revealed a slight increase in the resistance to acetic acid, suggesting a role of the eEF1A 5 N-terminal amino acids in the signalling of the protein to mitochondria and therefore in its function during the apoptotic process. Survival assay also showed that the expression of the eEF1A N1C146 or N1C177 fragments enhanced the susceptibility of the cells to acetic acid-induced apoptosis (Figure 25). Furthermore, the N1C177 fragment appears to have a more pronounced effect in this phenotype (Figure 25). Nevertheless, the expression of the eEF1A fragments without the apoptotic stimulus was not able to induced cell death. eEF1A is involved in different functions such as translation elongation and actin cytoskeleton

**Figure 25** – eEF1A N-terminal fragments N1C146 and N1C177 play pro-death function in cells challenged with acetic acid. (A) Scheme of the eEF1A fragments inserted in the p416 plasmid. (B) Comparison of the survival rate of wild-type *S. cerevisiae* cells expressing eEF1A total protein, N6C458 fragment and N-terminal N1C146 or N1C177 fragments upon treatment with 210 and 225 mM acetic acid.

organization and its fragmentation affects these processes which might contributing to the induction of the apoptotic process. On the other and, eEF1A N-terminal fragments pro-apoptotic role may only be activated upon their translocation to mitochondria, which only occurs during the apoptotic process. Moreover, eEF1A N-terminal fragments are probably downstream players on the apoptotic cascade, therefore an interaction with the upstream regulators, upon the triggering of apoptosis, is necessary for their pro-apoptotic function. To disclose the mechanism beneath this phenotype, eEF1A isoform *TEF1* deleted cells, harbouring a pYX222 plasmid expressing eEF1A full gene (N1C458) or eEF1A N-terminal fragment N6C177 (the eEF1A fragment that induced a more pronounced apoptotic phenotype) in frame with a mitochondrial localization sequence (MLS) in the N-terminal and a DsRed reporter in the C-terminal were transformed in *TEF1* deleted cells (Figure 26A, 26B). The *TEF1* deleted cells expressing the pYX222 empty vector proved to be more resistant to acetic acid treatment (Figure 26) that wild-

**Figure 26** – The pro-apoptotic function of eEF1A N-terminal fragment in the mitochondria is only active upon the acetic acid apoptotic stimulus. (A) Comparison of the survival rate of  $\Delta tef1$  *S. cerevisiae* cells expressing eEF1A total protein and N-terminal N6C177 fragment with a mitochondria localization sequence (MLS) in the N-terminal and a DsRed reporter in the C-terminal, upon treatment with 195, 210 and 225 mM acetic acid. (B) Confocal micrographs of strains used in (A) treated with 210 mM acetic acid in order to confirm the mitochondrial localization of the eEF1A protein and the N-terminal fragment.

type cells (Figure 25), suggesting the involvement of eEF1A in the apoptotic process. The eEF1A total protein and N6C177 fragment translocation to mitochondria was confirmed by confocal microscopy visualization of the DsRed expression in mitochondria under physiological conditions (Figure 26B). Nonetheless, no alteration in the cell survival and mitochondria morphology was observed upon the expression of eEF1A N6C177 fragment in mitochondria under these conditions (Figure 26B), proving that expression and translocation of eEF1A N6C177 fragment to mitochondria by itself is not capable of inducing apoptosis,

therefore ruling out our first hypothesis. However, acetic acid triggers an apoptotic cascade that might promote the pro-death role of eEF1A protein (Figure 26A). Protection conferred by the deletion of *TEF1*, when compared to wild-type cells (Figure 25), was abrogated upon the expression of eEF1A total protein during acetic acid treatment (Figure 26B), excluding also the second hypothesis. An even higher susceptibility to cell death was observed in cells expressing the eEF1A N6C177 fragment in mitochondria matrix (Figure 26A), supporting our third hypothesis and revealing eEF1A N-terminal N6C177 fragment as a downstream player in the apoptotic cascade. Despite that, confocal microscopy, could not confirm the eEF1A fragments localization in the mitochondria upon acetic acid treatment (Figure 26B). The reason for the observed DsRed degradation could rely on the cleavage of eEF1A N-terminal sequences, as occurs in the eEF1A total protein upon the apoptotic stimulus or the well described fission and degradation of mitochondria during acetic acid-treatment [39, 200, 201, 336]. Thus, the elucidation of the specific function exerted by these fragments and at which step of the mitochondrial acetic acid-induced apoptotic cascade they play a part, namely during the production of reactive oxygen species (ROS), reduction of mitochondrial potential, depolarization of mitochondria outer membrane, translocation of Aif1p from mitochondria to the nucleus, release of cytochrome *c* to cytosol, or mitochondrial fragmentation/degradation [41, 199, 200, 326, 328], is of utmost importance for the disclose of acetic acid-induced apoptotic cascade of events.

### siRNA-mediated eEF1A1 knockdown in HeLa cells leads to actin cytoskeleton alterations with increased susceptibility to apoptosis

Since previous results from our lab showed that the deletion of *TEF1*, but not *TEF2*, reverted the apoptotic phenotype induced by acetic acid in yeast and a decrease of the actin cytoskeleton alterations observed [290], we decided to evaluate if this phenomenon was evolutionarily conserved. Mammalian eEF1A isoforms, eEF1A1 and eEF1A2, are expressed mutually exclusive [337]. eEF1A2, is normally expressed only in muscles and neurons, being also related with tumor development in tissues that normally express only eEF1A1 [292, 309, 310, 312, 313, 338-340]. Both isoforms of eEF1A have been characterized to function in the protein elongation step of translation. However, eEF1A1, but not eEF1A2, has

**Figure 27** – Staurosporine (STS)-induced apoptotic cell death in HeLa cells. (A) Cell titer-blue cell viability assay of untreated and STS treated cells. (B) TUNEL assay of untreated and STS treated cells.

**Figure 28** – eEF1A RNAi depletion in HeLa cells increases susceptibility to staurosporine-induced apoptosis with actin cytoskeleton alterations. (A) Confirmation of the depletion efficiencies of eEF1A isoforms by immunoblot analysis. (B) Survival assay of untreated and STS treated cells upon eEF1A1, eEF1A2 and DRP1 RNAi depletions for 48h. (C) Immunofluorescence of eEF1A and actin protein expression levels.

additional non-canonical roles in actin binding/bundling [341]. Therefore, relevance of eEF1A isoforms in the actin cytoskeleton organization during the induction of apoptotic cell death was determined in HeLa cells, an immortalized human cell line of epithelial cells from cervical carcinoma. Mitochondrial fission-mediated apoptotic cell death was induced in HeLa cells using staurosporine (STS) [342]. In order to confirm the induction of apoptosis by STS in about 50% of HeLa cells in our experimental conditions, viability and TUNEL assays were performed after eighteen hours of incubation with 0.1  $\mu$ M of STS (Figure 27A, 27B). RNAi depletion of eEF1A1 and eEF1A2 isoforms and DRP1 (the mammalian homolog of yeast *DNM1*) was performed. Forty eight hours after transfection with the siRNAs, efficient repressions were ascertained as confirmed by immunoblot analysis of eEF1A levels (Figure 28A). Although silencing of eEF1A1 proved to be very efficient, the silencing of eEF1A2 produced almost no effect in eEF1A total levels (Figure 28A), suggesting that either eEF1A2 silencing was not efficient or eEF1A2 isoform levels in these cells are low as expected [309, 313]. The silencing of DRP1 affected the levels of eEF1A (Figure 28A) suggesting a regulation of eEF1A by DRP1. Furthermore, we evaluated the viability of RNAi cells exhibiting low/absent levels of eEF1A isoforms when treated with STS. In HeLa cells, the depletion of eEF1A1, but not of eEF1A2, increased the susceptibility to apoptotic cell death (Figure 28B), which could be explained by the fact that mRNA silencing is an immediate process leaving no time for cells to adapt to new conditions or because in mammalian cells these proteins perform a protective role upon the apoptotic stimulus. Furthermore, immunostaining of eEF1A and actin revealed actin cytoskeleton alterations in the absence of eEF1A1, the described actin binding/bundling protein in mammalian cells, (Figure 28C) and its complete destruction after STS treatment (data not shown). Therefore, similar to yeast, in mammalian cells eEF1A1, but not eEF1A2, is a crucial player in the regulation of actin cytoskeleton organization, playing also an important role in the apoptotic process. However, the suggested pro-apoptotic role of eEF1A in yeast is dissimilar from the protective role observed in mammalian cells. These antagonist roles are most likely due to the distinct apoptotic cell death pathways activated.

Nonetheless, these results demonstrate the relevance of eEF1A in the modulation of apoptosis both in yeast and mammalian cells.

### 3.4.2.2 The phosphorylation of eIF2 $\alpha$ and the levels of IF4A are not affected in $\Delta yca1$ cells challenged with acetic acid

Despite the observed metacaspase-independent cleavage and mitochondrial re-localization of eEF1A during acetic acid induced-apoptosis, the role of yeast metacaspase in other translation factors alterations upon acetic acid treatment was evaluated. For this purpose, an immunoblot kinetic analysis of eIF2 $\alpha$  phosphorylation levels and translation initiation factors eIF2 $\alpha$  (Sui2p), eIF4A (Tif1p) and eIF4G (Tif4631/2p) and translation elongation factor eEF2 (Eft1/2p) levels in  $\Delta yca1$  *S. cerevisiae* cells untreated or treated with 195 mM of acetic acid. Actin was used as loading control.

**Figure 29** - Yeast metacaspase (Yca1p) involvement in translation regulation during acetic acid-induced apoptosis. Immunoblot kinetic analysis of eIF2 $\alpha$  phosphorylation levels, translation initiation factors eIF2 $\alpha$  (Sui2p), eIF4A (Tif1p) and eIF4G (Tif4631/2p) and translation elongation factor eEF2 (Eft1/2p) levels in  $\Delta yca1$  *S. cerevisiae* cells untreated or treated with 195 mM of acetic acid. Actin was used as loading control.

levels in *YCA1* deleted cells upon acetic acid treatment was performed (Figure 29A). This experiment revealed a decrease in the phosphorylation levels of eIF2 $\alpha$  to a basal level upon acetic acid treatment (Figure 29), when compared to the wild-type cells (Figure 10A). Since in mammalian cells PERK kinase activation for the phosphorylation of eIF2 $\alpha$  is caspase-dependent [59, 72], and in yeast, the

deletion of *YCA1* reduced the Gcn2p-mediated phosphorylation of eIF2 $\alpha$ , a regulation of translation initiation through the control of Gcn2p kinase activity by metacaspase might be occurring. Moreover, the levels of eIF4A appeared almost unaltered when  $\Delta yca1$  cells were challenged with acetic acid suggesting once more a regulation of translation machinery by metacaspase during the apoptotic process (Figure 29). Despite this observation, no eIF4A fragmentation was detected by immunoblot analysis. Therefore, we could not infer if eIF4A is a metacaspase substrate or if it is indirectly regulated by this protease. The levels of eEF4G and eEF2 were also less affected (Figure 29) than in wild-type cells. However, this effect was not as notorious as the one observed in the eIF4A. Altogether, these data showed that translation machinery is also a target of yeast metacaspase, directly or indirectly, in scenarios of apoptotic cell death highlighting a new putative link, which deserves further investigation, between translational control and cell death.

Altogether these results show the relevance of metacaspase in the regulation of the translation during the apoptotic process. The down-regulation of translation initiation factors levels upon the apoptotic stimulus combined with the specific cleavage of GAPDH, which might lead to the derepression of an IRES-mediated translation, by metacaspase, strongly suggests metacaspase as an apoptotic upstream regulator of the translation process during acetic acid-induced apoptosis.

### 3.5 DISCUSSION

In mammalian cells, the targeting of translation machinery by caspases during apoptosis [59, 72, 83] is well established. In yeast, metacaspase seems to be one of the executors of the apoptotic events [214] despite its enigmatic role. The routes to unravel metacaspase functions undoubtedly have to pass through the identification of its specific substrates and how substrates cleavage is involved in the apoptotic phenotype. Therefore, using different methodologies, digestome and mutagenesis analysis, we studied the targeting of translation machinery by metacaspase during different scenarios of yeast apoptosis. A relation between metacaspase and apoptosis has been previously established during acetic acid-induced apoptosis since a metacaspase-dependent decapping of mRNA leading to mRNA degradation has been reported [218, 244, 246]. Digestome analysis revealed the first yeast metacaspase substrate, the glycolytic enzyme GAPDH, a common apoptotic substrate from yeast to mammalian [219]. GAPDH is S-nitrosated during  $\text{H}_2\text{O}_2$ -induced apoptosis [211]. Since metacaspase activity is dependent on the NO intracellular levels [212] and we show that GAPDH fragments appear nitrosated, similarly to what occurs in higher eukaryotic cells, a NO signalling appears to be regulating metacaspase substrates targeting [45]. Nonetheless, we were unable to identify the other spots observed below the diagonal, corresponding to other putative metacaspase substrates, and to disclose a role of metacaspase in the cleavage of translation machinery by this methodology. However, in mammalian cells a relation between translation impairment and the activation of a GAPDH mediated apoptotic pathway has been established [343]. Furthermore, the specific binding of this glycolytic enzyme to IRES of virus RNAs leading to the inhibition of virus RNA cap-independent translation in mammalian cells and blocking the viral infection has been widely reported [135-138], as well as the binding to mammalian cells mRNAs, such as the pro-apoptotic molecule p53 and AT1R [136, 317, 323, 344], impairing their IRES-mediated translation. The translation of several apoptotic regulators, both pro-apoptotic [101] and anti-apoptotic [109], is regulated by IRES. The cleavage of GAPDH by caspase-1 [139] upon an apoptotic stimulus might prevent its interference in the cap-independent translation crucial for the development of the

apoptotic process [4, 95, 243]. Therefore, the activation of metacaspase during acetic acid treatment leading to the cleavage of GAPDH might be an upstream regulatory mechanism to trigger an alternative cap-independent translation process mediated by IRES which in physiological conditions is repressed by the binding of GAPDH to the mRNAs. The elucidation of mRNAs target of GAPDH binding in yeast and the relevance of these interactions for the efficient translation of these mRNAs and consequently their function is of utmost importance for the understanding of the regulatory mechanisms mediating apoptosis.

The targeting of mitochondrial proteins by caspases during apoptosis in mammalian cells [322] prompted us to investigate a conservation of this regulation during yeast apoptosis. Analysis of mitochondrial proteomic profile revealed eEF2 protein and two N-terminal fragments of eEF1A in the purified mitochondrial fractions [290] of acetic acid-treated cells despite the decreased of eEF1A and eEF2 levels in total cellular extracts [215]. These data strongly suggested a role of these translation elongation factors in the apoptotic process and further studies were performed. Despite the fact that both eEF1A total protein and N-terminal fragments were found in the mitochondrial extracts, only the N-terminal fragments proved to be imported to the mitochondrial matrix. Moreover, the expression of these N-terminal fragments results in an increased susceptibility to acetic acid treatment, strongly suggesting the pro-apoptotic role of these fragments. The mitochondrial localization of eEF1A fragments raises the possibility that eEF1A is a key player in the promotion of the well described acetic acid-induced mitochondrial alterations, namely in the release of apoptotic factors, such as cytochrome c [199] and Aif1p [41]. Moreover, eEF1A translocation to mitochondria may have multiple implications for the cell, besides its role in the process of translation elongation, eEF1A plays a role in several other housekeeping processes [287, 345], such as actin cytoskeleton organization [295, 296]. During acetic acid-induced apoptosis the binding of eEF1A to actin proved to be compromised, which might affect actin conformational stability and therefore the actin cytoskeleton organization, ultimately leading to the induction of apoptosis. In fact, the decrease in the cytosolic levels of eEF1A during acetic acid-induced apoptosis led to alterations in the actin cytoskeleton [290] even though the F-actin structures were unaffected

[346]. The mammalian eEF1A isoform eEF1A1 was also shown to have a crucial role in STS-induced apoptosis in HeLa cells. In contrast to yeast, silencing of eEF1A1 mRNA increases susceptibility of HeLa cells to the apoptotic stimulus, suggesting the performance of a pro-survival role by eEF1A1, indicating that this translation factor is also an important player in mammalian cell death processes. Nevertheless, further studies using different apoptotic stimuli are crucial for a better understanding of the eEF1A role in apoptosis. Conservation of the eEF1A1-regulated actin cytoskeleton organization is also maintained from yeast to mammalian. Epifluorescence microscopy analysis reveals that silencing of eEF1A1 leads to alterations in the actin cytoskeleton, which are more pronounced upon the STS-induced apoptosis. These results suggest a role for the translation factor eEF1A unrelated to the translation process during the course of the apoptotic process both in yeast and mammalian in which eEF1A most likely acts as a pro- or anti-apoptotic proteins depending on the apoptotic process triggered. Nevertheless, in yeast, this role proved not to be mediated by metacaspase, unlike the alterations observed in levels of other translation factors during yeast acetic acid-induced apoptosis. Although a direct interaction and cleavage of translation factors by metacaspase could not be proven, an indirect regulation of eIF4A levels and of eIF2 $\alpha$  phosphorylation, suggests a regulation of Gcn2p kinase activity, by metacaspase during acetic acid-induced apoptosis.

The data obtained open new perspectives for the elucidation of the molecular cascade regulated by metacaspase activation. The specific cleavage of GAPDH, which in mammalian cells acts as a repressor of cap-independent translation, and the regulation of some translation factors levels, suggests a regulation of the translation process by this protease. Furthermore, the fragmentation of eEF1A and re-localization in mitochondria together with eEF2 suggest that during acetic acid-induced apoptosis, these factors are part of the apoptotic process leading to actin cytoskeleton alterations from yeast to mammalian cells.

## CHAPTER 4

National congresses:

- Microbiotec 11. Braga, Portugal. (2011). “HSP90: endogenous modulators of yeast acetic acid-induced apoptotic cell death”. (Poster presentation).

## 4.1 ABSTRACT

Global mRNA translation impairment has been described during the course of apoptosis both in mammalian and yeast cells. Nevertheless, the molecular pathways modulating translation during different scenarios of apoptosis are still largely unexplored. Polysome profile analysis during yeast acetic acid-induced apoptosis revealed a global impairment of translation, correlated to the phosphorylation of eIF2 $\alpha$  subunit by Gcn2 protein kinase (Chapter 2). Nevertheless, our previously reported proteomic analysis in the same apoptotic conditions revealed increased levels of heat shock protein 90 (HSP90) isoforms [215]. We herein demonstrate by microarray analysis of polysomal mRNAs combined with the HSP90 isoforms 5' untranslated region (5'UTR) expression in monocistronic reporter plasmids harboring an hairpin, that HSP90 isoforms are translated by a cap-independent mechanism mediated by internal ribosome entry site (IRES) elements in the 5'UTR of the mRNA. Genetic abrogation of HSP90 isoforms indicate divergent roles for HSP90 isoforms, Hsc82p acting as a pro-survival and Hsp82p as a pro-death molecule, in response to acetic acid treatment. Moreover, the deletion of *HSC82* leads to a severe necrotic cell death suggesting a role of these isoforms in the balance between apoptosis and necrosis, upon acetic acid treatment. These undisclosed functions of yeast HSP90 isoforms were confirmed through pharmacological inhibition of HSP90 activity, using 17-allylaminogeldanamycin (17AGG), and overexpression of each HSP90 isoform in acetic acid challenged cells. These results suggest that the efficiency of HSP90 isoforms mRNA translation is an important component of the cellular response to acetic acid. A role of HSP90 in the regulation of mammalian programmed cell death (PCD) has also been addressed, given the use of these proteins as attractive targets to cancer therapy. Our data show that different HSP90 isoforms are up-regulated depending on the drugs used to modulate the apoptotic cell death in the Acute Myeloid Leukaemia cell lines suggesting that, similar to yeast, in mammalian cells HSP90 isoforms play distinct functions.

## 4.2 INTRODUCTION

Programmed cell death (PCD) includes all types of cell death executed by regulated mechanisms and under rigorous molecular control, ranging from apoptosis to necrosis [27]. Nowadays, an increasing body of evidence is revealing the involvement of translation control in PCD processes [4, 76, 95, 243]. The specific fragmentation and/or alteration in the phosphorylation state of several translation factors during PCD [59, 286], prompts a selective cap-independent translation, mediated by internal ribosome-entry site (IRES) elements in the 5' untranslated region (5'UTR) of mRNAs, which directly recruit ribosomes independent of the interaction with the mRNA cap-structure [4, 109, 118, 347, 348]. Interestingly, in mammalian cells, IRES sequences were found in mRNAs of both inhibitors and inducers of PCD, such as XIAP and Apaf-1, respectively [101, 109]. In yeast, the knowledge on translational control of apoptosis is still scarce. During oxidative stress a reduction of global translation mediated by the phosphorylation of eIF2 $\alpha$  by Gcn2 kinase (the amino acid control kinase) has been described [220]. Moreover, during yeast nutrient starvation an eIF4G-dependent IRES-mediated translation of several genes is required for an efficient response to stress [227]. IRES were reported in yeast transcriptional regulators such as transcription factors *FLO8* [227] and *YAP1* [234], transcriptional activators *HAP4* [228] and *MSN1* [227] and transcriptional repressor *URE2* [230] being involved in the response to yeast stress stimulus.

Heat shock protein 90 (HSP90) chaperones are a family of highly conserved proteins with crucial functions in protein folding/refolding [141, 144, 349] as well as in regulation of the balance between autophagy and proteasome activity [188, 350-355], with a role in cell proliferation, apoptosis and necrosis [32, 141, 143, 172-174, 185, 188, 223]. It has been described that the binding of HSP90 to Apaf-1, inhibits the formation of the apoptosome, and therefore the induction of apoptosis [140, 167]. Moreover, the interaction of HSP90 with the death domain kinase receptor interacting protein (RIP) was proved to be crucial for inhibition of tumor necrosis factor (TNF)-induced cell death [173]. HSP90 inhibitors, such as allylaminogeldanamycin (17AGG) and radicicol, proved to prevent necrosis induction by Fas- and tumor-necrosis factor receptor 1 in mammalian cells [172,

173] and by tunicamycin in yeast [223]. Besides the already described functions of HSP90 chaperones, in yeast, these isoforms also interact with a wide number of proteins [356], being required for pheromone signaling [357], mitochondrial proteins delivery [147, 357], transcriptional regulation [225, 226, 358, 359], and translational control, namely ribosome biogenesis [358], mRNA stability [358] and Gcn2 kinase maturation and regulation [360]. Nonetheless, despite the HSP90 chaperones crucial role in cell death, the translation of HSP90 mRNAs mediated by IRES was never addressed neither in yeast nor in mammalian cells.

Herein we show the occurrence of a translational rearrangement during the progression of acetic acid-induced apoptosis with the activation of a cap-independent IRES-mediated translation regulation of the HSP90 isoforms expression, among several others molecules, and their antagonistic role in this apoptotic process.

## 4.3 MATERIALS AND METHODS

### Strains, media and treatments

*S. cerevisiae* strain BY4742 (*MATa his3Δ1 leu2Δ0 lys2Δ0 ura3Δ0*) and its respective *HSC82* and *HSP82* genes knockouts (EUROSCARF, Frankfurt, Germany) were used. For acetic acid treatment, *S. cerevisiae* cells were grown until the middle exponential phase in liquid YPD medium containing glucose (2%, w/v), yeast extract (0.5%, w/v) and peptone (1%, w/v). Cells were initially harvested, resuspended in fresh medium (pH 3.0) and incubated at 26°C for 1h. Then cells were resuspended ( $10^8$  cells/mL) in fresh medium (pH 3.0) followed by the addition of 180 or 195 mM acetic acid and incubation during 15, 30, 60, 120 and 200 min at 26°C with stirring (150 r.p.m.) with or without the presence of 10 and 100  $\mu$ M of 17-allylaminogeldanamycin (17AGG). After the 200 min treatment, approximately 300 cells were spread on YPD agar plates and viability was determined by counting colony forming units after 2 days of incubation at 26°C [199]. Cells were also harvested to further studies described below.

For construction of the Hsc82p- and Hsp82p-overexpressing strains, *HSC82* and *HSP82* were amplified by PCR (*HSC82* primers 5'-

GGATCCATGGCTGGTGAAACTT-3' and 5'-ATCGATTAAAGATCTTCTTCAGA-3, *HSP82* primers 5'-GGATCCGGAAGCTTGATGACAGA-3' and 5'-ATCGATTAAAGATCTTCTTCAGAA-3') using genomic DNA, isolated from *HSP82* and *HSC82* deleted cells, respectively, and cloned into the BamHI and ClaI sites of pUG35 (EUROSCARF, Frankfurt, Germany), which displays a MET25 promoter, generating pUG35*HSC82* and pUG35*HSP82*.  $\Delta hsc82$  cells were transformed with pUG35*HSC82* and  $\Delta hsp82$  cells with pUG35*HSP82*, generating strains *HSC82*<sup>overexp</sup> and *HSP82*<sup>overexp</sup>, respectively. *HSC82*<sup>overexp</sup> and *HSP82*<sup>overexp</sup> cells were grown until exponential growth phase (OD<sub>640nm</sub>=0.5) on synthetic complete (SC) medium containing glucose (2%, w/v), yeast nitrogen base (0.17%, w/v, Difco), 300 mg/L of L-leucine, 50 mg/L of L-histidine and 50 mg/L of L-lysine at 26°C with stirring (150 r.p.m.). Cells were washed, resuspended in fresh SC medium (pH 3.0), treated with 160, 180 and 210 mM of acetic acid and incubated for 200 min at 26°C with stirring (150 r.p.m.).

**Table 6** - List of primers for construction of p281 monocistronic plasmids.

Gene	Primer sequences

For construction of p281*HSC82*, p281*HSP82*, p281*TIF4632* and p281*CLN3* plasmids, DNA encoding *HSC82*, *HSP82*, *TIF4632* and *CLN3* 5'UTR was amplified by PCR using the primers described in Table 6, digested with BamHI and EcoRI, and cloned by homologous recombination into p281 vector at the 5'UTR of a  $\beta$ -galactosidase (LacZ) reporter gene with (p281h) or without a stable hairpin in the 5'UTR, and under the control of the GAL1/10 promoter [230, 361, 362].  $\Delta hsc82$  cells were transformed with p281 empty vector, p281h empty vector, p281h*HSC82* 5'UTR, p281h*TIF4632* or p281h*CLN3* plasmid and  $\Delta hsp82$  cells p281 empty vector, p281h empty vector, p281h*HSP82* 5'UTR,

p281hTIF4632 or p281hCLN3 plasmid. Cells were grown until exponential growth phase ( $OD_{640nm}=0.5$ ) on synthetic complete (SC) medium containing glucose (2%, w/v), yeast nitrogen base (0.17%, w/v, Difco), 300 mg/L of L-leucine, 50 mg/L of L-histidine and 50 mg/L of L-lysine. Cells were washed, resuspended in SC medium containing galactose (2%, w/v) and incubated at 26°C or 37°C with stirring (150 r.p.m.) for 18 hours.

Mammalian cells, namely, HL-60 and Jurkat cell lines, were cultured in DMEM medium (Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum (FBS), 1% glutamax, and 1% antibiotics mixture (Invitrogen) and grown at 37°C in a 5% CO<sub>2</sub> humidified chamber.

### **Polysome profile analysis**

Yeast cells were grown to middle exponential phase and treated with acetic acid as described above. Five min before cells being harvested, cycloheximide (CHX) was added to a final concentration of 100 µg/mL to freeze protein synthesis elongation, cells were collected, washed twice and disrupted using lysis buffer [20 mM Tris at pH 8.0, 140 mM KCl, 1.5 mM MgCl<sub>2</sub>, 0.5 mM DTT, 100 µg/mL CHX, 1 mg/mL heparin and 1% Triton X-100] and glass beads (Sigma). 40 units A<sub>280nm</sub> were loaded onto 11 mL 15 - 50 % sucrose gradients containing 20 mM Tris-HCl at pH 8.0, 140 mM KCl, 5 mM MgCl<sub>2</sub>, 0.5 mM DTT, 100 µg/mL CHX and 500 µg/mL heparin. Gradients were centrifuged using a SW41 rotor (Beckman-Coulter) at 35000 rpm for 2 hours and 45 min at 4°C. Polysomal profiles were visualized by monitoring RNA absorbance at 254nm using a Bio-Rad Biologic LP system adapted for this use. Monosomal and polysomal fractions of the gradient were collected into tubes containing 8M guanidine-HCl and stored at – 80 °C. In order to obtain sufficient quantity of mRNA for microarrays analysis, identical fractions were pooled into a single tube.

### **Polysomal RNA preparation**

Polysomal mRNA was precipitated with ethanol 85%, extracted using phenol: chloroform and precipitated, first with 1.5 M lithium chloride (LiCl) for removing

any residual heparin, and then with 100% ethanol plus 110 mM sodium acetate, pH 5.3.

## RT-PCR analysis

Total RNA isolated from both polysome profile fractions and mammalian cell lines reverse transcription to cDNA was carried out using the First-Strand cDNA synthesis kit (GE Biosciences). The quantitative PCR was performed on a CFX96 Touch real-time thermocycler (Bio-Rad) using SsoFast EvaGreen Supermix (Bio-Rad) and gene-specific primers as described in Table 7.

Relative expression levels were determined using the standard curve method. Controls lacking reverse transcriptase (RT) demonstrated no significant genomic DNA amplification.

### Microarrays analysis

Reverse transcription, cDNA transcription, cRNA labelling with Cyanine 3-CTP and hybridization was carried out using the One-Color Microarray-Based Gene Expression Analysis (Low Input Quick Amp Labeling) kit (Agilent Technologies). Before hybridization, free dye was removed using RNeasy mini spin columns (Quiagen), and the efficiency of cRNA synthesis and dye incorporation (labelling efficiency in pmol Cy3/ $\mu$ g cRNA) was measured by spectrophotometry (NanoDrop 1000, Thermo Fisher Scientific). Each hybridization was carried out using 600 ng of Cyanine 3-labelled cRNAs and the Yeast Gene Expression Microarray (V2: G4813A, Agilent Technologies), for 17 hours at 65°C, in an Agilent hybridization oven. Microarrays were scanned using the Agilent DNA Microarrays Scanner G2565AA and raw data was extracted using the Agilent feature extraction protocol GE1\_105\_Dec08 (PerkinElmer).

### Data normalization and analysis

Using the normalized M values (log<sub>2</sub> ratios) obtained, statistical differences were calculated using the *t*-test. Differentially expressed genes were identified for a False Discovery Rate below 0.001 (FDR < 0.001). Functional analysis of expression data obtained was done using Expander software. The data sets were submitted to ArrayExpress (<http://www.ebi.ac.uk/arrayexpress/>).

## **Immunoblot**

For immunoblot analysis, untreated or acetic acid-treated cells were collected and disrupted using glass beads in lysis buffer [1% v/v Triton X-100, 120 mM NaCl, 50 mM Tris-HCl pH 7.4, 2 mM EDTA, 10% v/v Glycerol, 1 mM PMSF and Complete Mini protease inhibitor cocktail (Roche, Mannheim, Germany)]. From total protein extracts, 40 µg were resolved on a 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to a nitrocellulose membrane (Amersham) over 90 min at 100 V. Membranes were then probed with polyclonal rabbit Ser51 phosphorylated eIF2α antibody (1:2000, Upstate), monoclonal rat anti-HSP90 (1:1000, Calbiochem) and polyclonal goat anti-actin (1:5000, kindly provided by Campbell Gourlay). Horseradish peroxidase (HRP)-conjugated anti-rabbit, anti-rat and anti-goat IgG secondary antibody were used, at a dilution of 1:5000 and detected by enhanced chemiluminescence.

## **β-galactosidase activity (LacZ)**

LacZ activity was measured following the protocol described in the Clontech Yeast Protocols Handbook using O-nitrophenyl-β-D-galactopyranoside (ONPG) as a substrate. Cells were disrupted using glass beads in Z buffer [60 mM Na<sub>2</sub>HPO<sub>4</sub>·7H<sub>2</sub>O, 40 mM NaH<sub>2</sub>PO<sub>4</sub>·H<sub>2</sub>O, 10 mM KCl, 1 mM MgSO<sub>4</sub>·7H<sub>2</sub>O, 0.27% (v/v) β-mercaptoethanol].

## **TUNEL assay**

DNA strand breaks were assessed by a TUNEL assay with the In situ Cell Death Detection Kit, POD (Roche Applied Science, Indianapolis, IN). Yeast cells were initially fixed with 3.7% formaldehyde followed by digestion of the cell walls with lyticase. After preparation of cytopspins, the slides were rinsed with PBS, incubated in permeabilization solution (0.1%, v/v, Triton X-100 and 0.1%, w/v, sodium citrate) for 3 min on ice, rinsed twice with PBS, and incubated with 10 µL of TUNEL reaction mixture (terminal deoxynucleotidyl transferase and FITC-dUTP) for 60 min at 37°C. Finally, the slides were rinsed three times with PBS and a coverslip was mounted with a drop of anti-fading agent Vectashield (Molecular Probes, Eugene, OR) and with 2 µL of 50 µg/mL propidium iodide (PI, Molecular

Probes) solution in Tris buffer (10 mM, pH 7.0) with  $\text{MgCl}_2$  (5 mM) and RNase (0.5  $\mu\text{g/mL}$ ). Cells were visualized with an Olympus PlanApo 60X/oil objective, with a numerical aperture of 1.42.

### **Statistical analysis**

Arithmetic means of cell survival rates are presented with standard deviation with a 95% confidence value. Statistical analysis was carried out using independent samples *t*-test analysis. A *p*-value <0.05 was assumed to denote a significant difference.

## **4.4 RESULTS**

### **4.4.1 Microarray analysis of mRNAs translated during acetic acid treatment**

Data herein presented showing that the elongation factors and eIF4G levels were unaffected for a long period of the acetic acid treatment (Figure 10), together with our previous proteomic data revealing that some protein levels are increased under the same conditions [215], suggests that acetic acid treated cells are capable of cap-independent translation. Thus, microarray profiling of polysomal mRNAs of acetic acid treated cells was assessed (Figure 30). With this purpose, RNA was extracted from independent cultures, polysomal profile was performed and polysomal fractions (Figure 30A), corresponding to the fractions in which mRNAs are being actively translated, were collected for further RNA purification, reverse transcription, labeling using Cy3 and hybridized to Agilent Yeast Gene Expression Microarray (V2:G4813A). The data obtained were submitted to ArrayExpress. Data analysis revealed different translational profile at 0, 15 and 30 min (Figure 30B, 30C, 30D). A 2-fold cut-off value was used to analyse the transcriptomics by cross-time point's comparison. The mRNA profile of polysomal fractions revealed 323 mRNAs up-regulated genes (Figure 30BI - blue dots) and 132 down-regulated mRNAs (Figure 30BI – red dots) after 15 min of acetic acid treatment, corresponding to 5.1% and 2.1% of the total number of mRNAs analysed (6392 genes in the array), respectively. After 30 min of treatment the cluster of the mRNAs altered showed only 165 up-regulated mRNAs (Figure 30BII

**Figure 30** - Microarray analysis of mRNAs translated during acetic acid treatment. (A) Polysomal fractions (PF) of the polysomal profiles of yeast wild type cells untreated (0 min) or treated with acetic acid for 15 min and 30 min collected for microarray and RT-PCR analysis. (B) Graphical representations of the translational microarray data for mRNAs altered from 0 to 15 min (I), 0 to 30 min (II) and 15 to 30 min (III) of acetic acid treatment. The mRNAs in polysomal fractions at 15 min or 30 min of acetic acid treatment ( $\log_2$  PF) have been plotted against the mRNAs in polysomal fractions at 0 min of acetic acid treatment (control). Venn diagram of the (C) upregulated and (D) downregulated mRNAs at 15 min and 30 min of acetic acid treatment when compared with control. The data sets were submitted to ArrayExpress (<http://www.ebi.ac.uk/arrayexpress/>).

- blue dots) and 176 down-regulated mRNAs (Figure 30BII - red dots). These mRNAs correspond to 2.6% and 2.7% of the total number of genes mRNAs analysed, respectively. The clustering of the mRNAs altered from 15 to 30 min revealed 28 up-regulated mRNAs (Figure 30BIII - blue dots) and 71 down-regulated mRNAs (Figure 30BIII - red dots) corresponding to 0.65% and 1.11% of the total number of mRNAs analysed.

A Venn diagram for the up- and down-regulated mRNAs at 15 and 30 min of acetic acid treatment was obtained corroborating the dot plots presented. The Venn diagrams showed that from 15 to 30 min 88 mRNAs are maintained up-regulated and 31 down-regulated (Figure 30C and 30D). These results showed that up-regulation of some mRNAs is maintained from 15 to 30 min, but most of the altered mRNAs at each time point was different, suggesting the occurrence of a remodelling of the translational process during the period from 15 to 30 min of the acetic acid treatment. The data points to an active translation of specific mRNAs under conditions of cap-dependent translation impairment.

The acetic acid treatment induces a progressive decline of survival along the treatment time course (Figure 8A), compatible with a first response to the imposed stress and a later activation of the apoptotic cell death. Therefore, after 15 min of acetic acid treatment most of the up-regulated mRNAs are probably involved in the cells response to the acid stress. mRNAs up-regulated after 15 min of acetic acid treatment revealed several known apoptotic regulators such as the anti-apoptotic *CDC48* [189] and *SAP30* [363] and the pro-apoptotic *FIS1* [200], among other mRNAs such as the translation initiation factors eIF3 (*TIF34*), responsible for the ribosome scanning, and eIF4G (*TIF4632*), important for the IRES-mediated translation (Attachment II, Table 1). At this time point we could also detect *HSC82*, *ILV3*, *LYS7* and *THR1* which were also found upregulated in a proteomic analysis of acetic acid treated cells [215], and *CAF20*, a described inhibitor of cap-dependent translation [364] through the interaction with eIF4E (Attachment II, Table 1). However, at 30 min of acetic acid treatment about 20% of the cells have lost the proliferative capacity being committed to death. Thus, the up-regulated mRNAs at this time point may also be involved in the activation and progression of the apoptotic cascade. After 30 min of acetic acid treatment up-regulation of

*CAP20*, *CDC48*, *SAP30* and *HCS82* is maintained, as well as other mRNAs such as *DNM1*, involved in acetic acid-induced mitochondrial fission [200], and the *HSP82* chaperone, also found up-regulated in the proteomic analysis [215]

**Figure 31** – Validation of microarray data by RT-PCR analysis of selected genes. Microarray and RT-PCR data are shown for up-regulated mRNAs *CAF20* and *TIF34* and down-regulated mRNAs *CIT2* and *COX3* in polysomal fractions from yeast cells challenged with acetic acid for 0, 15 and 30 min. The values are expressed relative to untreated control cultures and are the means of triplicate microarray and RT-PCR determinations.

(Attachment II, Table 3). Since at 15 and 30 min of acetic acid treatment a heterologous population of cells mounting a response to the acid stress and cells activating the apoptotic cascade is present, it is expected that in the microarray analysis mRNAs involved in both process are found up-regulated under the regulation of a cap-independent translation.

The microarrays results were validated by RT-PCR analysis of mRNAs found altered in the polysomal fractions of the acetic acid treated cells using the same RNA samples. In fact, RT-PCR analysis confirmed the general tendency detected by microarray analysis (Figure 31). For this validation both mRNAs found up-regulated and down-regulated in the polysomal fractions at 15 and 30 min of acetic acid treatment were used. We were able to confirm the up-regulation of *TIF34* and *CAF20* mRNAs and the down-regulation of *COX3* and *CIT2* mRNAs *oth* at 15 and 30 min of incubation with acetic acid. Although some variation in the levels of each mRNA was observed from microarray to RT-PCR analysis, the tendency of the levels of each mRNA is maintained in both analyses (Figure 31).

#### 4.4.2 Functional classification of mRNAs regulated during acetic acid treatment

Microarray results were also analysed and grouped into functional categories according to the Expander software TANGO tool and the *Saccharomyces* Genome Database GO Term Mapper ([db.yeastgenome.org/cgi-bin/SGD/GO/goTermMapper](http://db.yeastgenome.org/cgi-bin/SGD/GO/goTermMapper)).

**Figure 32** - Functional analysis of the regulated mRNAs in microarray analysis of yeast cells treated with acetic acid during 15 min (15') and 30 min (30').

Fifteen minutes of incubation with acetic acid induced the translation of mRNAs involved in different functional categories such as translation with the up-regulation

of the initiation factors eIF3, eIF4G, and the inhibitor of cap-dependent translation, *CAF20* [364] and several structural constituents of the ribosomes (Figure 32 and Attachment II, Table 1). On the other hand, several of the reduced mRNAs at 15 min participate in different metabolic processes such as transport, organophosphate, lipid and carbohydrate metabolism (Figure 32 and Attachment II, Table 2). However, functional categories analysis of the mRNAs whose expression was up-regulated at 30 min, revealed a shorter list of activated functions, exposing mainly cellular functions related to the ribosomal biogenesis and regulation of the translation process (Figure 32 and Attachment II, Table 4).

At 30 min of acetic acid treatment besides the up-regulation of *HSC82* mRNA, already detected at 15 min, *HSP82* mRNA was also increased, suggesting a role for HSP90 chaperones in acetic acid response. Heat shock protein 90 (HSP90) isoforms, *HSC82* and *HSP82* were both found up-regulated during acetic acid treatment suggesting a role for HSP90 chaperones in acetic acid-induced apoptosis which will be further investigated.

#### **4.4.3 HSP90, IRES chaperones translated during acetic acid treatment**

mRNAs encoding molecular chaperones HSP90, namely *HSC82* and *HSP82* were found up-regulated in the polysomal fractions of yeast cells challenged with acetic acid, both by microarrays analysis and by RT-PCR (Figure 33A). The *HSC82* mRNA levels at 15 min were higher than those from *HSP82*, about 4 fold, but at 30 min this effect was reverted and *HSP82* mRNA levels increased about 25 fold (Figure 33A). In fact, the percentage of *HSC82* and *HSP82* mRNA in monosomal and polysomal fractions was not altered upon 15 min or 30 min of acetic acid treatment (Figure 33C, 33D), demonstrating that although cap-dependent translation initiation was impaired (Figure 8, 9, 10), this did not affect HSP90 isoforms translation. The increased HSP90 isoforms mRNAs detected in polysomal fractions was shown to have an imprint in total cellular RNAs (Figure 33E) and protein levels (Figure 33F). The RT-PCR analysis of total cellular RNA, performed in acetic acid treated cells revealed an increase in the levels of both isoforms, *HSC82* and *HSP82*, dependent on the concentration of acetic acid tested (Figure 33E). Supporting the data obtained in polysomal fractions, *HSP82* displayed

**Figure 33** - HSP90 isoforms translation during acetic acid treatment. (A) Microarray and RT-PCR of *HSC82* and *HSP82* mRNAs levels in polysomal fractions from yeast cells challenged with acetic acid for 0, 15 and 30 min. The values are expressed relative to untreated cultures and are the means of triplicate microarray and RT-PCR determinations. (B) Illustration of the polysomal fractions from which mRNAs were extracted and analysed by RT-PCR (M, monosomal fraction; P1, P2, P3 and P4, polysomal fractions). RT-PCR of (C) *HSC82* and (D) *HSP82* mRNA expression in polysomal fractions demonstrate their translation upon 15 min treatment with acetic acid. (E) RT-PCR analysis of *HSC82* and *HSP82* expression in total mRNA of yeast cells after 200 min acetic acid treatment. (F) Immunoblot kinetic analysis of HSP90 in wild type cells after treatment with acetic acid.

higher relative mRNA levels when compared to *HSC82* (Figure 33E). Although immunoblot analysis did not allow the discrimination between Hsc82p and Hsp82p, the kinetics showed an increase of HSP90 isoforms levels in acetic acid-treated cells (Figure 33F). The levels of HSP90 progressively increased from 15 up to 60 min of acetic acid treatment after what a slight decrease was observed (Figure 33F).

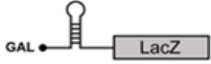

These results showed that *HSC82* and *HSP82* mRNAs are translated during the acetic acid treatment, in spite of the cap-mediated translation impairment observed under these conditions (Figure 8, 9, 10), raising the question of whether or not these mRNAs could be translated by a cap-independent mechanism.

In mammalian cells, the presence of IRES in the 5'UTR of mammalian apoptotic regulators mediating their translation during an apoptotic stimulus has been described [4, 95-97, 99, 101, 108, 109, 111, 118, 243, 348, 365, 366]. In yeast, IRES are present in mRNAs of several transcriptional regulators controlling their contribution for an efficient stress response [227, 228, 230, 234]. However, the activation of this alternative translation mechanism has never been addressed in yeast apoptotic conditions. Thus, the increased mRNAs and protein levels of HSP90 isoforms observed during acetic acid treatment, despite the translation initiation impairment, led us to hypothesized that 5'UTR of HSP90 isoforms mRNA might enclose IRES sequence(s) mediating their efficient translation during acetic acid treatment.

To test whether the 5'UTR of HSP90 isoforms mRNA harbor IRES sequence(s) and are capable of internal translation initiation, the 5'UTR of *HSC82* and *HSP82* were inserted in-frame between the *GAL1* gene promoter and the mRNA of  $\beta$ -galactosidase (LacZ) reporter gene of monocistronic plasmids containing a stable hairpin structure, which abolishes cap-dependent translation (Figure 34) [230, 361]. These constructs were transformed in *HSC82* mutant cells or in *HSP82* mutant cells according to the 5'UTR in study. The determination of the LacZ reporter activity was assessed in cells after 18h of galactose induction at 26°C and at 37°C, the latter is a condition known to inactivate eIF4E activity and thus the cap-dependent translation [230]. As expected, constructs encoding LacZ mRNA with a 5'UTR derived from the *GAL1* gene (p281 empty) [230, 361]

showed a high translation efficiency at 26°C and a significant decrease upon incubation at 37°C in both strains (Figure 34). Insertion of a stable hairpin structure in the 5'UTR [230, 361] (p281h empty) resulted in a significant

Construct	<i>Δhsc82</i> LacZ activity		<i>Δhsp82</i> LacZ activity	
	26°C	37°C	26°C	37°C
 	10341 (±2806)	2768 (±198)	9065 (±1546)	2215 (±253)
 	313 (±80)	28 (±10)	261 (±126)	16 (±5)
 	302 (±32)	494 (±116)	-	-
	-	-	3617 (±1051)	2283 (±381)

**Figure 34** - HSP90 isoforms translation mediated by IRES. Expression of *HSC82*, *HSP82*, *TIF4642* and *CLN3* 5'UTR tagged with a  $\beta$ -galactosidase (LacZ) reporter gene in monocistronic plasmids under the control of the GAL1/10 promoter. LacZ activity (relative milliunits) was determined after 18 h induction of the cells in 2% galactose at the indicated temperature.

reduction of LacZ activity (Figure 34). Control plasmids harboring the *CLN3* 5'UTR, negative control [234], and *TIF4632* 5'UTR, positive control previously reported to harbor IRES in the 5'UTR [227], were constructed and transformed in both strains (Figure 34). *TIF4632* 5'UTR promoted an efficient translation as revealed by LacZ activity whereas *CLN3* 5'UTR did not display any IRES activity as demonstrated by the absence of LacZ activity (Figure 34).

The LacZ activity was significantly higher in cells expressing monocistronics plasmids under the control of *HSC82* 5'UTR or *HSP82* 5'UTR in the presence of a stable hairpin both at 26°C and 37°C (Figure 34). These results indicated that the *HSC82* 5'UTR and *HSP82* 5'UTR harbor IRES that allow a competent translation in conditions of cap-dependent translation impairment promoted either by the

presence of a stable hairpin or by the inhibition of eIF4E binding at the cap-structure at 37°C (Figure 34).

Altogether, these data reveal a new regulatory mechanism controlling translation during acetic acid treatment, a condition that we have previously shown to inhibit cap-dependent translation (Chapter 2). Furthermore, this IRES-mediated translation regulates HSP90 isoforms expression and most likely is involved in the regulation of the HSP90 increased mRNA levels observed during acetic acid treatment.

#### **4.4.4 Modulation of HSP90 isoforms expression suggests a dual role of these chaperones in response to acetic acid**

The data presented strongly suggests that Hsc82p and Hsp82p are translated by a cap-independent mechanism upon acetic acid treatment in conditions known to induce 50% of cell death [191, 215]. Thus, the contribution of these isoforms for the apoptotic process was studied. For such purpose, the susceptibility/resistance of *HSC82* and *HSP82* mutant cells to acetic acid treatment was determined. Deletion of *HSC82* resulted in an increased susceptibility while deletion of *HSP82* augmented the resistance to acetic acid treatment compared to wild-type cells (Figure 35A). These results indicate opposing roles for Hsc82p and Hsp82p in response to acetic acid treatment. Expression of *HSC82* or *HSP82* under a MET promoter in the respective deleted strains showed functional complementation and a reversion of the phenotype (Figure 35B and 35C). Due to the promoter's strength not only the phenotypes of the deleted cells were reverted but also Hsc82p was able to confer additional protection and Hsp82p to increase susceptibility to acetic acid (Figure 35B, 35C). These results strongly support antagonist roles for the HSP90 isoforms during acetic acid treatment. Hsc82p is suggested to be involved in a pro-survival pathway activated as a stress response while Hsp82 seems to be enrolled in a pro-death function upon acetic acid treatment. To further elucidate the HSP90 isoforms functions, wild-type, *hsc82Δ* and *hsp82Δ* cells were challenged with acetic acid in the presence of a HSP90 inhibitor, 17-allylaminogeldanamycin (17AGG). The inhibition of HSP90 in *HSP82* deleted cells had no effect on cell

**Figure 35** - Modulation of HSP90 isoforms expression suggests opposite roles for these chaperones during acetic acid treatment. (A) Comparison of the survival rates of wild type,  $\Delta hsc82$  and  $\Delta hsp82$  *S. cerevisiae* cells after acetic acid treatment. Analysis of the survival rates of (B)  $\Delta hsc82$  and (C)  $\Delta hsp82$  *S. cerevisiae* cells harboring a pUG35 plasmid expressing *HSC82* or *HSP82*, after treatment with acetic acid. (D) Comparison of the survival rates of wild type,  $\Delta hsc82$  and  $\Delta hsp82$  *S. cerevisiae* cells treated with 180 mM of acetic acid after pharmacological inhibition of HSP90 activity, using 17-allylaminogeldanamycin (17AGG). (E) Propidium Iodide (PI) staining of wild type,  $\Delta hsc82$  and  $\Delta hsp82$  *S. cerevisiae* cells after acetic acid treatment (180 mM) measured by flow cytometry. (F) Epifluorescence and bright field micrographs of untreated and acetic acid-treated (180 mM) wild-type,  $\Delta hsc82$  and  $\Delta hsp82$  cells displaying TUNEL reaction to visualize double-strand DNA breaks. Cells were co-stained with propidium iodide in order to facilitate nuclei visualization. Bar, 5  $\mu$ m.

survival but in wild-type cells it resulted in increased acetic acid induced cell death and in *HSC82* deleted cells led to a moderated protection (Figure 35D). These data reinforce the opposite roles performed by the HSP90 isoforms in response to

acetic acid and attributes a pro-survival role for Hsc82 and a pro-death role for Hsp82.

The evaluation of the type of programmed cell death (PCD) occurring in each of the above described strains showed that despite the higher susceptibility to acetic acid treatment demonstrated by the *HSC82* deleted cells, almost no TUNEL-positive cells were observed by microscopy analysis (Figure 35F), contrarily to the well described phenotype of TUNEL-positive staining in the wild-type cells [191]. Moreover, propidium iodine (PI) staining of *HSC82* deleted cells revealed a high percentage of PI positive cells (Figure 35E), which did not occur in the *HSP82*-disrupted cells (Figure 35E), meaning that the membrane integrity of *HSC82* mutated cells was affected, therefore suggesting the occurrence of a necrotic cell death. These data also suggests that HSP90 isoforms are key molecules in governing the balance between apoptotic and necrotic cell death when cells are challenged with acetic acid. In yeast, HSP90 chaperones have been implicated in the modulation of necrotic cell death [221, 223], pointing Hsp82p as the HSP90 isoform involved in yeast necrotic cell death.

#### **4.4.5 HSP90 regulation of Gcn2p kinase activity during acetic acid-treatment**

Among the described functions of HSP90, these chaperones have a crucial role in the maturation and regulation of Gcn2p kinase activity [360]. HSP90 interaction with Gcn2p is abolished in conditions leading of accumulation of uncharged tRNAs such as amino acid starvation, derepressing the mature Gcn2p mediated phosphorylation of the subunit  $\alpha$  of the translation initiation factor 2 (eIF2 $\alpha$ ) and consequently leading to the inhibition of cap-dependent translation [360]. However, the treatment of cells with 17AGG inhibits HSP90 activity and its release from Gcn2p, blocking the function of Gcn2p in the phosphorylation of eIF2 $\alpha$  and translation regulation [360]. Since translation impairment has been observed upon acetic acid treatment, mediated by the Gcn2p kinase regulation of eIF2 $\alpha$  phosphorylation (Figure 10, 11), we hypothesized if the role of HSP90 chaperones in response to acetic acid was related with the regulation of the Gcn2p kinase activity. To evaluate this hypothesis, immunoblot kinetic analysis of eIF2 $\alpha$

**Figure 36** – HSP90 regulate Gcn2p activity at early time points of the acetic acid treatment. Immunoblot kinetic analysis of eIF2α phosphorylation in (A) wild-type *S. cerevisiae* cells after treatment with 195 mM acetic acid upon pharmacological inhibition of HSP90 activity using 17AGG, and in (B)  $\Delta hsc82$  or (C)  $\Delta hsp82$  cells treated with 195 mM acetic acid.

phosphorylation levels in *HSC82* and *HSP82* deleted cells and wild-type cells treated with 17AGG, was performed. The results obtained showed a delay in the phosphorylation of eIF2α in all the conditions upon acetic acid treatment (Figure 36) when compared to wild-type cells (Figure 10A), suggesting a role of HSP90 isoforms in the regulation of Gcn2p kinase activity in the first time point of acetic acid treatment, crucial for the early inhibition of cap-dependent translation initiation. However, at later time points this regulation does not occur, which could be explained by the recruitment of HSP90 chaperone for modulation of the acetic acid-induced apoptosis, and interaction with other client proteins.

#### 4.4.6 HSP90 chaperones isoforms differential expression in mammalian cell lines

Mammalian cells contain three types of HSP90 chaperones: cytosolic HSP90, mitochondrial HSP90 (Trap-1), and endoplasmic reticulum HSP90 (Grp94) [367]. Prominent members of mammalian cytosolic HSP90 family are Hsp90alpha (HSP90AA-1, HSP90AA-2, and HSP90AB1) and Hsp90beta (HSP90B1) isoforms [141]. Hsp90beta is expressed constitutively to a higher level than Hsp90alpha, which is generally stress-inducible [141]. HSP90 chaperones are the only HSPs targeted in cancer therapy, namely in Acute Myeloid Leukemia (AML) therapy [186, 188], using the inhibitor of HSP90 activity, 17AGG.

**Figure 37** – HSP90 isoforms expression pattern in leukemic cell lines. RT-PCR analysis of mammalian HSP90 isoforms (HSP90AA1-1, HSP90AA1-2, HSP90AB1, HSP90B1 and HSP90N) mRNA levels in Jurkat and HL-60 cell lines.

However, the outcome is below expectations, probably due to the indiscriminated inhibition of HSP90 isoforms, instead of targeting the isoform(s) specifically implicated in AML. Our results showed that yeast HSP90 isoforms, Hsc82p and Hsp82p, are IRES-mediated translated, upon global translation impairment during PCD. The yeast data also showed the divergent roles played by each HSP90 isoform during PCD. Since HSP90 are conserved proteins from yeast to mammalian, with analogous described behavior and functions [141, 143, 188], it is of utmost importance to understand the contribution of each mammalian HSP90 isoform for the PCD process. Thus, the levels of each HSP90 isoform in human

**Figure 38** – HSP90 isoforms expression profile in leukemic cell lines. RT-PCR analysis of mammalian HSP90 isoforms (HSP90AA1-1, HSP90AA1-2, HSP90AB1, HSP90B1 and HSP90N) mRNA levels, relative to untreated cells, in (A) Jurkat and (B) HL-60 cell lines treated with 17AAG, rapamycin, chloroquine, doxorubicin or cytarabine.

leukemic cell lines, the AML HL-60 cell line and the acute T-lymphoblastic leukemia Jurkat cell line, were assessed. Results showed a similar pattern of expression of each HSP90 isoform both in HL-60 and Jurkat cell lines (Figure 37). However, leukemic cell lines treatment with drugs involved in the modulation of distinct cellular processes revealed the upregulation of distinct HSP90 isoforms (Figure 38A, 38B). The 17AGG inhibits HSP90 activity [174, 178, 186, 368], rapamycin inhibits TOR pathway and therefore activates the autophagic process [267, 272, 369-373], chloroquine inhibits the autophagic process [276, 277, 374], bortezomib inhibits the proteosome [375], and doxorubicin and cytarabine are two drugs widely used in AML therapy [376-379]. The data analysis revealed differential expression of the HSP90 isoforms correlated with the drug tested (Figure 38). The inhibition of HSP90 activity led to the accumulation of HSP90AA1-2 and HSP90AB1 mRNAs in the cell and the decrease in the levels of

HSP90AA1-1 and HSP90B1 mRNAs both in Jurkat and HL-60 cell line (Figure 38). In physiological conditions HSP90AA1-2 and HSP90AB1 mRNAs are more expressed than the other isoforms in these cell lines (Figure 37) and the inhibition of their activity might lead to the accumulation of correspondent mRNAs in the cell which will not be recruited for translation (Figure 38A, 38B). Activation of autophagy has been correlated with the decrease of the HSP90 activity [353, 355], which corroborated our results showing a decrease in the levels of all the HSP90 isoforms when cells were treated with rapamycin (Figure 38). The inhibition of autophagy using chloroquine did not induce a significant increase of HSP90 isoforms levels, with the exception of HSP90AB1 isoform which presented higher levels in Jurkat cell line (Figure 38A). Moreover, inhibition of proteasome by bortezomib induced an increase in the levels of HSP90AA1-2, HSP90AB1 and HSP90B1 in Jurkat cells (Figure 38A). However, the induction of apoptosis mediated by doxorubicin led to an increase in the levels of HSP90AA1-1 isoform and downregulation of all the others, particularly in HL-60 cells (Figure 38B). Cytarabine treated cells displayed higher levels of HSP90A1-1 and HSP90B1 isoforms in Jurkat cells and decrease in the expression of all the isoforms in HL-60 cells (Figure 38A, 38B).

These results combined suggest that each HSP90 isoform plays a distinct role in the cell, and depending on the stimulus distinct isoforms are activated. Using drugs known to affect the inter-regulatory processes of autophagy and ubiquitin-proteasome system, the HSP90 isoform HSP90AA1-2 and specially the isoform HSP90AB1 appear to be recruited and activated as modulators of these processes. However, drugs involved in the modulation of other pathways such as doxorubicin induce the translation of HSP90AA1-1 isoform. Doxorubicin and 17AGG, two drugs used in cancer therapy triggering two different apoptotic processes [160, 170, 173, 186, 379-384], induce the expression of different isoforms of HSP90, strongly suggesting the targeting of different client proteins by each HSP90 isoform involved in distinct molecular pathways. Therefore, the unveiling of the specific proteins interacting with each HSP90 isoform will allow a better understanding of the mechanism regulating HSP90 isoforms functions in the cell for a more efficient cancer therapy with less secondary effects.

## 4.5 DISCUSSION

Over the past few years, the involvement of the translation process in the regulation of apoptosis has emerged as a crucial mechanism both in mammalian and yeast cells [59, 95, 215, 220]. Since translation is the final stage in the course of genetic information, regulation at this level leads to a direct response to changes in physiological conditions. During yeast *S. cerevisiae* acetic acid-induced apoptosis, a general amino acid starvation occurs [215] and a translation reduction might allow cells to conserve resources for a quick rearrangement of the gene expression in response to the stimulus. Microarrays kinetic analysis of polysomal mRNAs translated during acetic acid treatment, showed a decrease in the mRNA levels throughout the experiment. However, it revealed a list of up-regulated mRNAs at 15 and 30 min of acetic acid treatment, putatively involved in the cellular response to the acid stress or in the activation of the apoptotic process, since this analysis was performed at time points in which only a small percentage of the cells are undergoing apoptosis. HSP90 isoforms, *HSC82* and *HSP82*, were found upregulated in the polysomal mRNAs, although *HSP82* presented a higher fold change than *HSC82* after 30 min of acetic acid treatment. Furthermore, insertion of HSP90 isoforms 5'UTR and eIF4G at the 5'UTR of a monocistronic LacZ reporter gene harboring a hairpin showed us that translation of these chaperones as well as of eIF4G is mediated by the presence of IRES in the 5'UTR of the mRNAs allowing the translation of these isoforms by a cap-independent mechanism upon the apoptotic stimulus. These results corroborate all the previous results, pointing for the activation of an alternative IRES-mediated translation upon inhibition of cap-dependent translation during acetic acid treatment, controlling the translation of HSP90 and eIF4G. Nevertheless, the Hsc82p and the Hsp82p isoforms appear to play antagonist roles during the apoptotic process. Hsc82p play an anti-apoptotic and Hsp82p a pro-apoptotic function upon acetic acid treatment. Moreover, a balance between the two isoforms levels, during acetic acid treatment is crucial for the induction of apoptosis. The absence of Hsc82 leads to a necrotic cell death upon acetic acid treatment, probably due to the absence of an anti-apoptotic factor to balance the effect of the pro-apoptotic factor Hsp82. A role for HSP90 chaperones in the modulation of yeast necrotic cell death has been

addressed [223]. Moreover, interaction between the pro-apoptotic isoform Hsp82p and the yeast homologue of mammalian caspases, metacaspase, has been reported [209]. Therefore, a study of the role of Hsp82p in the folding of metacaspase upon its activation during the apoptotic process should be performed. Moreover, the dual role of HSP90 chaperones may be related with the fact that the different isoforms are responsible for the folding/refolding of different proteins playing distinct roles in different physiological conditions. HSP90 chaperones are target molecules for cancer therapy [141, 159, 174, 181, 185, 186, 188, 385]. The fact that in yeast, the two known isoforms of HSP90 chaperones, Hsc82p and Hsp82p, play distinct roles in the modulation of apoptotic cell death, and due to the high conservation of HSP90 chaperones from yeast to mammals [141, 143], it is of utmost importance to understand the individual relevance of mammalian HSP90 chaperones for the PCD process in an integrated view using mammalian cells, namely AML cell lines. In fact, the levels of HSP90 isoforms, HSP90AA1-1, HSP90AA1-2, HSP90AB1, HSP90B1 and HSP90N, in cells treated with different drugs which target distinct cellular processes previously associated with a modulation of the apoptotic process [170, 177, 277, 374, 375, 384, 386-388], suggest that each HSP90 isoform has specific targets being involved in different processes which might be related to cell death or survival. These results suggest once more a conservation in the pathways/mechanism regulating PCD from yeast to mammalian cells, highlighting yeast as a good model for the study of apoptosis. Thus, future investigations using mammalian cells for the elucidation of the translation mechanisms regulating HSP90 expression, such as IRES, and the contribution of each HSP90 isoform to the PCD process is crucial for the screen of new drugs that directly act against the HSP90 isoform(s) involved in the disease for a more targeted less aggressive treatment.

Altogether, our findings reveal a new apoptotic regulatory mechanism mediated by the balance between the levels of HSP90 isoforms, Hsc82p and Hsp82p, in the presence of an apoptotic stimulus. This balance appears to be tightly regulated by the activation of an alternative mechanism of *HSC82* and *HSP82* isoforms mRNA translation mediated by the IRES sequences present in their 5'UTR. The simultaneous IRES-mediated translation of both isoforms, with

antagonistic roles in the cell during acetic acid treatment further supports a conservation of the translation regulatory mechanisms from yeast to mammalian cells placing yeast as a powerful tool in the study of the mechanism underlying the regulation of cap-independent translation during apoptosis.

## CHAPTER 5

---

### **Concluding remarks and future perspectives**

## 5.1 FRAMEWORK OF THE RESULTS

During evolution, organisms have to adapt to the surrounding environment in order to perpetuate the species, a mechanism called natural selection that Charles Darwin also liked to call “Survival of the fittest” [389]. Despite the divergent adaptation strategies undertaken by the different organism throughout evolution, they share the same origin, the same molecular basis. Therefore, the main basic and housekeeping molecular pathways regulating cells fate are most likely conserved.

The phenotypical alterations induced by the activation of different types of programmed cell death (PCD), as apoptosis and necrosis, both in yeast and mammalian cells are widely recognized [27, 28, 30]. However, the knowledge of the molecular pathways behind these phenotypes is a continuous challenge in constant update. By itself this is an intricate task, and the fact that different PCD stimuli lead to the activation of distinct PCD pathways makes it even more complex.

Over the last years, the translation process has been described as a crucial piece in mammalian cells PCD puzzle [95, 348]. Alterations in the translation machinery, such as the fragmentation of translation initiation factors eIF3, eIF4B, eIF4G mediated by caspases and post-translational modifications of eIF2 $\alpha$  and eIF4E leading to the inhibition of the cap-dependent translation during the PCD process [59] prompt an alternative translation mechanism. This alternative translation is regulated by the presence of internal ribosome entry site (IRES) elements, usually at the 5' untranslated region (5'UTR) of the mRNAs, which directly recruit ribosomes independent of the mRNA cap-structure [235, 390] but may also require the participation of canonical translation initiation factors such as the eIF4G, eIF4A, eIF3 and eIF2 $\alpha$  [5, 227, 232, 235, 391-396]. IRES-mediated translation proved to be critical for cellular homeostasis and regulation of the cells fate upon triggering of the PCD process [4]. These sequences have been described not only in mRNAs related with the activation of the cell death cascade such as p53 [119], APAF-1 [109], c-myc [112], DAP5 [118] but also in mRNAs involved in the cell survival such as XIAP [132], HIAP2 [98], Bcl-2 [122] and HSP70 [125].

In yeast, the study of IRES-mediated translation is still an emergent field and a correlation between IRES and PCD has not yet been made. Nonetheless, IRES sequences have been identified in several mRNAs related to response to stress through transcriptional regulation, such as *FLO8* a transcription factor [227], *YAP1* [234], *HAP4* [228] and *MSN1* [227] transcription factors and activator, respectively, involved in the response to oxidative stress, *URE2* a transcriptional repressor of genes involved in nitrogen catabolism [230], and eIF4G, a translation initiation factor crucial for yeast IRES-mediated translation [227].

## 5.2 TRANSLATION MODULATING OF YEAST PCD

A conservation in translation machinery alterations during apoptosis from yeast to mammalian cells was established by the observation of an impairment in translation initiation at early time points of acetic acid treatment through a drastic decrease in translation initiation factor eIF4A levels and the increased phosphorylation of eIF2 $\alpha$  mediated by Gcn2p kinase, a key player in this apoptotic process. In mammalian cells, the phosphorylation of eIF2 $\alpha$  is a common feature of different apoptotic processes [67, 72, 108, 242, 397] as well as in the response to stress conditions allowing cells to initiate a remodeling of the gene expression for a effective stress response [66, 108, 398]. The eIF2 $\alpha$  phosphorylation or even a specific cleavage can be also mediated by caspases in the course of the apoptotic cascade as a mechanism of global translation inhibition [59, 64, 72, 399], allowing the activation of the IRES-mediated translation process [131, 390]. In yeast, the phosphorylation of eIF2 $\alpha$  proved to be implicated in the apoptotic process since the deletion of *GCN2*, the only kinase described to be responsible for the phosphorylation of eIF2 $\alpha$  in yeast [253, 256, 260, 261], leads to an increased resistance to acetic acid treatment together with a drastic decrease in the phosphorylation levels of eIF2 $\alpha$ . Similar to what has been described in mammalian cells, during acetic acid treatment eIF2 $\alpha$  phosphorylation is part of a regulatory process which inhibits global translation giving space for the activation of a selective IRES-mediated translation. In mammalian cells, IRES-mediated translation also requires the participation of canonical translation initiation factors

which vary with requirement of the IRES-containing mRNAs [4, 5]. Therefore, the analysis of our data suggests that eIF4A is not required for an IRES-mediated translation during acetic acid treatment, since the levels of this translation initiation factor decrease after 15 min of acetic acid treatment. On the other hand, the levels of eIF4G are maintained until later time points of the apoptotic process. In fact, in higher eukaryotes, IRES-mediated translation with the participation of eIF4G, with or without the interaction of eIF4A has been described [5, 400]. These evidences together with the fact that, in yeast, eIF4G is an IRES-containing factor involved in the efficient IRES-mediated translation in response to stress [227], further consolidates our hypothesis that an eIF4G-dependent IRES-mediated translation of mRNAs required for the apoptotic process, such as *AIF1*, occurs during acetic acid treatment.

Similar to mammalian cells apoptotic process, the alterations observed in translation initiation factors eIF4A and eIF2 $\alpha$  upon acetic acid challenge appear to be mediated by metacaspase, the yeast homologue of mammalian caspases [40]. However, if this effect is mediated by the direct interaction of metacaspase with the translation factors, inducing their cleavage, or through indirect regulation of their levels is still not known and further studies should be performed. Nevertheless, metacaspase digestome analysis revealed a metacaspase substrate, the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH). The extensive fragmentation of this enzyme during yeast apoptosis has been previously reported [211, 219, 401], but an association of this event to yeast metacaspase had never been made [219]. In mammalian cells, this enzyme is a known inhibitor of virus and mammalian mRNAs IRES-mediated translation [119, 134-138]. Hence, GAPDH is responsible for the inhibition/repression of cap-independent IRES-mediated translation in higher eukaryotes as a protective mechanism against opportunistic viral infections and apoptosis. Its specific cleavage by caspase-1 in mammalian cells [139] and metacaspase in yeast [219] in apoptotic conditions strongly suggests that GAPDH fragmentation might be crucial for the progression of IRES-mediated translation of apoptotic regulators mRNAs, emerging as a putative repressor of this translation mechanism both in yeast and mammalian cells. In order to clarify this possible regulation further studies are required.

Although we observed a loss-of-function by some of the translation initiation factors, such as eIF2 $\alpha$  and eIF4A, other translation factors appear to have a gain-of-function upon the apoptotic stimulus, being recruited for the modulation of other processes, which might be unrelated with translation. That is the case of eEF1A and eEF2, which are fragmented and translocated to mitochondria during acetic acid treatment. eEF1A N-terminal fragments are even imported to the mitochondrial matrix where they appear to perform a pro-apoptotic function. Mitochondria are organelles known to contain a separate protein synthesis machinery [402-404]. In fact, most of the mitochondrial transcription/translation machinery and proteins are synthesized in cytosol and imported to mitochondria [304, 327, 402-412]. Therefore, the specific translocation of eEF1A and eEF2 translation elongation factors fragments to mitochondria during acetic acid treatment might be a part of mitochondrial apoptotic cascade leading to the described severe mitochondrial alterations, such as the production of reactive oxygen species (ROS), depolarization of mitochondria outer membrane, translocation of Aif1p from mitochondria to the nucleus and release of cytochrome c to cytosol, culminating in mitochondria fission and fragmentation/degradation [41, 199, 200, 326, 328]. The recruitment of these factors might also be related with an alternative mitochondrial translation mechanism of important apoptotic regulators in hypothetical conditions of mitochondrial canonical translation factors degradation. Since eEF1A N-terminal fragments codify for the GTP-binding domain involved in the delivery of the aminoacyl-tRNAs to ribosomes and eEF2 is involved in ribosomal translocation during protein synthesis their participation in the aminoacyl-tRNA delivery to mitochondria and translation elongation during apoptosis might be of great contribution for this process and should be further investigated.

In order to identify the mRNAs capable of being translated by the IRES-mediated translation, a screening of putative IRES-containing mRNAs translated during acetic acid treatment was performed. This study allowed us to confirm the presence of IRES in the 5'UTR of HSP90 isoforms, *HSC82* and *HSP82*, as well as in the eIF4G exposing an alternative IRES-mediated mechanism controlling HSP90 chaperones translation during acetic acid treatment. Similar to what occurs during

yeast nutrient-starvation [227], eIF4G IRES-mediated translation during acetic acid-induced amino acid starvation strongly suggests the participation of eIF4G in the IRES-mediated translation initiation, similar to what has been described regarding the IRES-mediated translation of several mammalian mRNA [5, 90, 95, 393, 394, 396, 413, 414].

Despite that, HSP90 isoforms individual translation appears to activate distinct cellular pathways. Hsc82p acts as a pro-survival molecule and Hsp82p as a pro-death molecule despite their high sequence identity (96%) and shared contribution for the regulation of Gcn2p activity during the earlier time points of the acetic acid treatment. Since these chaperones are involved in the folding/refolding of several client proteins involved in the regulation of several different processes [144, 162, 225, 226, 356-358, 360, 415-431], their antagonist role during acetic acid treatment might be related with their regulation of distinct processes, activating opposite responses to acetic acid treatment. In fact, the interaction of Hsp82p with the yeast metacaspase has been reported [209], suggesting the participation of Hsp82p in the acetic acid-induced apoptosis through interaction/folding of the active metacaspase, regulating its function in the cell. Since HSP90 are also involved in the protein delivery to mitochondria [149], a contribution of these chaperones for the translocation of eEF1A or eEF2 to mitochondria upon the apoptotic stimulus might occur. This is an aspect that deserves further attention.

In mammalian cells, a deregulation of HSP90 levels has been associated to disease [140, 162, 177, 186, 432-437], such as in acute myeloid leukemia (AML) [146, 432]. Pharmacological modulation of distinct cellular pathways using different drugs, namely 17-allylaminogeldanamycin (17AGG), a specific-inhibitor of HSP90 activity, rapamycin, the inhibitor TOR and an inducer of autophagy, chloroquine, an inhibitor of autophagy, bortezomib, an inhibitor of the proteasome and doxorubicin and cytarabine, the common AML chemotherapeutic drugs, revealed the activation of distinct isoforms of HSP90. These results strongly suggest that each HSP90 isoform interacts and is responsible for the folding of distinct proteins involved in different cellular pathways and processes [438]. In fact, similar to what occurs in yeast, in mammalian cells HSP90 chaperones are

**Figure 39** - Proposed illustrative scheme of the cell death pathway triggered by acetic acid, based on the main findings reported in this thesis. Dashed lines represent hypothesis that, although supported by our experiments, require further investigation.

involved in the regulation of distinct processes and client proteins. HSP90 regulate the function of proteins involved in the cell survival such as Survivin [161], RIP [173], Bcr-Abl [153, 186, 439, 440], Akt [153, 156, 433, 441], Zap-7 [164], rp53 [350], p23[442], cdc37 [163] and Raf-1 [443], among others, or in the cell death such as Apaf-1 [167] and FKBP38 [171]. A deregulation of HSP90 isoforms levels in the cell may affect their interaction with client proteins leading to a rupture of the cellular homeostasis. Therefore, a thorough study of the HSP90 isoforms alternative translation mechanisms, specific client proteins and the involvement of these proteins in the disease are of utmost importance for development of a more efficient treatment for AML and other diseases related to HSP90 deregulation.

Summing up, during acetic acid treatment an intracellular amino acid starvation occurs, blocking of TOR pathway which induces a derepression of the Gcn2p kinase. The Gcn2p active kinase phosphorylates eIF2α inhibiting the formation of

the translation initiation ternary complex (Figure 39). Activation of metacaspase directly or indirectly reduces the levels to eIF4A and regulates the phosphorylation of eIF2 $\alpha$ , probably through interaction with Gcn2p (Figure 39). These alterations associated with the translation of Caf20p, an eIF4E binding protein, inhibit the cap-dependent translation initiation (Figure 39). The specific cleavage of GAPDH by metacaspase might favor the translation of the IRES-containing mRNAs, mediated with the participation of the canonical translation factor eIF4G, also harboring IRES (Figure 39). This mechanism will enable the translation of HSP90 in conditions of cap-dependent translation initiation impairment and their participation in the modulation of the acetic acid-induced apoptosis, Hsc82p playing a pro-survival and Hsp82p a pro-death role (Figure 39). Furthermore, at latter time points, the re-localization of eEF2 and eEF1A to mitochondria occurs, possibly regulated by HSP90 chaperones, which has also been associated with mitochondrial proteins delivery [147, 149]. eEF1A is fragmented and two of these fragments corresponding to eEF1A N-terminal sequences are imported to the mitochondria, where appear to be involved in the apoptotic process which will induced the mitochondria fission/fusion (Figure 39). The translocation of eEF1A to mitochondria reduces its binding to actin a consequently to actin cytoskeleton organization alterations. The combination of all these events culminates in the yeast cell death (Figure 39).

### 5.3 IMPLICATIONS FOR FUTURE RESEARCH

Altogether, the results presented in this thesis yield new insights into the translation mechanisms regulating yeast PCD, opening new perspectives for future investigations.

Microarray analysis generated a large amount of data regarding the mRNAs translated during acetic acid treatment, revealing several possible regulators of the cellular response to acetic acid treatment, namely mRNAs involved in the response to the acid stress and mRNAs involved in the activation of the acetic acid-induced apoptotic process. These mRNAs translation might be regulated by IRES. Since we have only focused in the function of the two HSP90 isoforms, Hsc82p and

Hsp82p, these data constitute a powerful database (submitted to ArrayExpress (<http://www.ebi.ac.uk/arrayexpress/>) for future studies.

It would be also important to clarify the role to metacaspase in the translation machinery alterations observed during acetic acid treatment. The study of the specific interactions of metacaspase with translation factors and the Gcn2p kinase is of utmost importance for the elucidation of the regulatory mechanisms controlling the remodeling of the translation process from cap-dependent to cap-independent translation. With that purpose, specific digestome analysis of translation factors with active metacaspase, followed by immunoblot analysis should be performed in order to disclose if eIF4A and eIF2 $\alpha$  among other translation factors are in fact substrates of metacaspase during acetic acid treatment. Studies of cap-dependent and IRES-mediated translation efficiency in the absence of metacaspase, using metacaspase deleted strain, would also contribute for the disclosure of this protease role in the modulation of translation.

HSP90 chaperones play a preponderant role in cellular homeostasis. Therefore, the knowledge on the alternative translation mechanisms regulating HSP90 isoforms expression and the identification of their specific client proteins, as well as the effect of these interactions in the cell, is of great importance both in yeast and mammalian cells. The investigation of an IRES-mediated regulation of HSP90 isoforms translation in mammalian cells should be addressed. Furthermore, a yeast two-hybrid assay of HSP90 isoforms interactors both in yeast and in mammalian cells could be of great value in the understanding of the molecular pathways affected by each isoforms. In mammalian cells this information would allow a more targeted and effective cancer therapy.

The data obtained from these hypothetical experiments might be of great contribution for the continuous expansion on the knowledge of regulatory pathways controlling the apoptotic process.

Yeast metacaspase

Glyceraldehyde-3-phosphate dehydrogenase

Nitric oxide

## ABSTRACT

Yeast metacaspase (Yca1p) is required for the execution of apoptosis upon a wide range of stimuli. However, the specific degradome of this yeast protease has not been unraveled so far. By combining different methodologies described as requisites for a protein to be considered a protease substrate, such as digestome analysis, cleavage of recombinant GAPDH by metacaspase and evaluation of protein levels in vivo, we show that upon H<sub>2</sub>O<sub>2</sub>-induced apoptosis, the metabolic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is a specific target of metacaspase. Nitric oxide (NO) signaling, which mediates H<sub>2</sub>O<sub>2</sub>-induced apoptosis, is required for metacaspase specific GAPDH cleavage. In conclusion, in this work we identified GAPDH as the first direct yeast metacaspase substrate described so far. Although mammalian caspases and yeast metacaspase apparently have distinct target cleavage sites, GAPDH arises as a common substrate for these proteases.

## 1. Introduction

Over a decade ago, a family of proteases presenting structural similarities to caspases was identified in protists, fungi and plants [1]. These proteases were named metacaspases and classified, according to the presence or absence of a N-terminal prodomain containing a proline-rich repeat motif, as type I or type II, respectively. In spite of the structural similarity with the remotely related caspases, a large body of accumulating evidence shows that all metacaspases are highly specific for P1-Arg and P1-Lys substrates (reviewed in [2]).

Yeast cells have a single gene, *YCA1*, encoding a type I metacaspase that was first implicated in the execution of oxidative stress induced cell death [3] but that is estimated to participate in approximately 40% of the described yeast apoptotic scenarios [4]. Nevertheless, non-death functions have also been assigned to yeast metacaspase such as cell cycle regulation [5] and protein catabolism [6]. Although the mechanisms regulating this multifunctional protein, metacaspase,

still remain elusive, it is known that metacaspase activity is regulated through S-nitrosation and thus dependent on the endogenous levels of nitric oxide (NO) [7]. S-nitrosation of one metacaspase Cys residue keeps it inactive. However, a second catalytic Cys residue, highly conserved in all known metacaspases but absent in all members of caspases, can rescue metacaspase activity in the presence of high NO levels [7]. Accordingly, in yeast H<sub>2</sub>O<sub>2</sub>-induced apoptotic conditions [3,8], a cell death process dependent on metacaspase activity and NO generation, metacaspase activity and cell death are abolished in the presence of L-NAME, an inhibitor of NO synthesis [9,10].

One of the major mechanistic challenges for understanding the role of metacaspases in cell survival and death is still the identification of their natural substrates. At the present the only protein found to be cleaved by metacaspases in vivo is the evolutionarily conserved TSN (Tudor staphylococcal nuclease) [11] found in all eukaryotes except in budding yeast [11]. Thus, although in yeast, metacaspase is essential for apoptosis execution upon a wide range of either physiological or external stimuli [3,12], the substrates targeted by this protease are still unknown.

In this context, the identification of yeast metacaspase specific degradome is crucial for unraveling the signaling pathways regulated by yeast metacaspase and to clarify its function in cell death. Using a digestome analysis, together with in vitro and in vivo protein processing assays, we found evidence indicating that the yeast metabolic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is a specific substrate of yeast metacaspase.

**Abbreviations:** Yca1p, metacaspase; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; NO, nitric oxide; L-NAME, No-nitro-L-arginine methyl ester

## 2. Materials and methods

### 2.1. Yeast strains and plasmids

*Saccharomyces cerevisiae* BY4742 (*MAT $\alpha$  his3 $\Delta$ 1 leu2 $\Delta$ 0 lys2 $\Delta$ 0 ura3 $\Delta$ 0*) strain and its isogenic derivative  $\Delta yca1$  (EUROSCARF, Frankfurt, Germany) were used. For construction of the metacaspase-overexpressing strain, YCA1 was amplified by PCR (primers 5'-ccgggaattcgatgtatccaggtagtgacgt-3' and 5'-ccggggatccctacataat aaattgcagattacgtc-3'), using genomic DNA, isolated from BY4742 strain and cloned into the EcoRI and BamHI sites of pGREG546 (EUROSCARF, Frankfurt, Germany), which displays GST at N-terminal and a galactose-inducible promoter, generating pGREG546YCA1. Strain  $\Delta yca1$  was transformed with pGREG546YCA1, generating strain YCA1<sup>overexp</sup>.

### 2.2. Metacaspase overexpression and activation

YCA1<sup>overexp</sup> cells were grown until exponential growth phase ( $OD_{640nm} = 0.5$ ) on synthetic complete (SC) medium containing glucose (2%, w/v), yeast nitrogen base (0.17%, w/v, Difco), 300 mg/l of L-leucine, 50 mg/l of L-histidine and 50 mg/l of L-lysine. Cells were washed, resuspended in SC medium containing galactose (2%, w/v) and incubated at 26 °C with stirring (150 r.p.m.) to induce metacaspase overexpression. After 16 h,  $10^7$  cells/ml were harvested and resuspended in fresh SC medium with galactose (2%, w/v), and metacaspase was activated by the addition of 2 mM of H<sub>2</sub>O<sub>2</sub> [3] and incubation for 200 min at 26 °C with stirring (150 r.p.m.).

### 2.3. Inhibition of NO production

Inhibition of NO production was achieved by pre-incubation of yeast cells for 1 h with the non-metabolized L-arginine analog, N $\omega$ -nitro-L-arginine methyl ester (L-NAME; Sigma-Aldrich), as described [8,9].

### 2.4. Protein extracts

Total protein extracts were prepared from untreated and H<sub>2</sub>O<sub>2</sub>-treated yeast cells as described [9]. Protein concentration was determined by Bradford method [13].

### 2.5. Digestome analysis

Digestome analysis was performed according to the methodology previously described in [14], with adaptations. Four hundred micrograms of total protein extracts obtained from untreated wild-type yeast cells were resolved by SDS-PAGE 12% (first dimension). After migration, the lanes were excised and treated as described in [14], soaked in digestion buffer [50 mM Tris-HCl, 150 mM NaCl and 10 mM DTT] with 5 mg of either active metacaspase-enriched extracts (obtained from H<sub>2</sub>O<sub>2</sub>-treated YCA1<sup>overexp</sup> cells) or inactive metacaspase-enriched extracts (obtained from H<sub>2</sub>O<sub>2</sub>-treated  $\Delta yca1$  or untreated YCA1<sup>overexp</sup> cells), incubated overnight at 37 °C, washed with ultrapure water and incubated in loading buffer [50 mM Tris (pH 6.8), 2% SDS, 0.1% bromophenol blue, 10% glycerol, 2.5%  $\beta$ -mercaptoethanol] for 10 min at 95 °C. After cooling, lanes were subjected to a second dimension SDS-PAGE. Proteins in the gels were immunoblotted as described below or stained using Colloidal Blue Staining Kit (Invitrogen) and the spots located below the diagonal, corresponding to cleaved proteins, were excised from the gels and identified by MALDI-TOF mass spectrometry as described in [13].

### 2.6. Assessment of intracellular reactive oxygen species (ROS)

Free intracellular ROS were detected with dihydrorhodamine 123 (DHR123) (Molecular Probes, Eugene, OR, USA). DHR123 was added

from a 1 mg/ml stock solution in ethanol, to  $5 \times 10^6$  cells/ml suspended in PBS, reaching a final concentration of 15  $\mu$ g/ml. Cells were incubated for 90 min at 30 °C in the dark, washed in PBS and analyzed by flow cytometry. Flow cytometric assays were performed on a BD LSR II™ (Becton Dickinson, NJ, USA) using BD FACSDiva Software 6.0 (Becton Dickinson, NJ, USA). Twenty thousand cells per sample were analyzed using the FlowJo software (Tree Star, Ashland, OR, USA).

### 2.7. TUNEL assay

DNA strand breaks were assessed by a TUNEL assay with the In situ Cell Death Detection Kit, POD (Roche Applied Science, Indianapolis, IN). Yeast cells were initially fixed with 3.7% formaldehyde followed by digestion of the cell walls with lyticase. After preparation of cytospins, the slides were rinsed with PBS, incubated in permeabilization solution (0.1%, v/v, Triton X-100 and 0.1%, w/v, sodium citrate) for 3 min on ice, rinsed twice with PBS, and incubated with 10  $\mu$ L of TUNEL reaction mixture (terminal deoxynucleotidyl transferase and FITC-dUTP) for 60 min at 37 °C. Finally, the slides were rinsed three times with PBS and a coverslip was mounted with a drop of anti-fading agent Vectashield (Molecular Probes, Eugene, OR) and with 2  $\mu$ L of 50  $\mu$ g/mL propidium iodide (PI, Molecular Probes) solution in Tris buffer (10 mM, pH 7.0) with MgCl<sub>2</sub> (5 mM) and RNase (0.5  $\mu$ g/mL). Cells were visualized with an Olympus PlanApo 60X/oil objective, with a numerical aperture of 1.42. For quantification of the number TUNEL-positive cells, at least 400 cells from three independent assays were counted. Data express the percentage of TUNEL-positive cells compared to the total number of counted cells.

### 2.8. Recombinant protein expression and cleavage assay

For production of recombinant GAPDH, yeast GAPDH (*TDH3*) was amplified by PCR (primers 5'-ggggacaagttgtacaaaaagcaggtccatggttagagttgctatt-3' and 5'-ggggaccactttgtacaagaaagctgggtcttaagccttggaacgtg-3') from wild-type genomic DNA. PCR product was then inserted into pDEST17 vector (Invitrogen) using the gateway® technology (Invitrogen), generating the plasmid pDEST17GAPDH. *E. coli* strain BL21 pLys was transformed with vectors pDEST17GAPDH or pET23aYCA1 (kindly provided by Dr. E. Lam).

Recombinant GAPDH and metacaspase expression was induced with 1 or 0.4 mM isopropyl-1-thio- $\beta$ -D-galactopyranoside (IPTG), respectively, at 37 °C (GAPDH) or 28 °C (metacaspase). GAPDH was obtained as inclusion bodies that were solubilised in 50 mM Tris-HCl, 0.2 M NaCl, 2 mM EDTA, pH 8.0. Refolding conditions were screened using the iFOLD Protein Refolding System 2 (Novagen). The protein was refolded by dilution in 50 volumes of refolding buffer [50 mM TAPS, pH 8.5, 1.5 M Sorbitol, 24 mM NaCl, 1 mM KCl, 1 mM TCEP] overnight at 22 °C with mild agitation. Bacterial cells expressing YCA1 were broken by sonication as described in [15], and the resulting supernatants used as described hereafter.

Metacaspase cleavage of GAPDH was assayed by incubating 500  $\mu$ L of recombinant GAPDH in refolding buffer with 20  $\mu$ L of bacterial extracts obtained upon expression of metacaspase and 520  $\mu$ L of 2 $\times$  buffer A [0.2% (w/v) CHAPS, 0.2 M HEPES, 20% (w/v) Sucrose, 20 mM TCEP, pH 7.5]. As a negative control, GAPDH was incubated with bacterial extracts obtained from *E. coli* cells expressing the empty vector, pET23a, and as a positive control, 500  $\mu$ L of recombinant GAPDH in refolding buffer was mixed with 100  $\mu$ L of sea bass recombinant active caspase-1 in refolding buffer and with 600  $\mu$ L of 2 $\times$  buffer A. Samples were incubated overnight at 22 °C, precipitated with trichloroacetic acid, resolved by SDS-PAGE and immunoblotted.

### 2.9. Immunoblotting

Proteins in the gels were transferred to nitrocellulose membranes. Total protein extracts were probed with monoclonal mouse anti-

GAPDH (MAB474, Chemicon) as described [9] or with the monoclonal goat anti-actin (kindly provided by Dr. C.W. Gourlay) at a dilution of 1:5000. IgGs on the blots were detected with horseradish peroxidase-conjugated anti-mouse, anti-rabbit or anti-goat IgG secondary antibodies (Cell Signaling Technology) using an enhanced chemiluminescence kit (Pierce). The expression of active metacaspase in *E. coli* harboring the pET23aYCA1 plasmid was confirmed using polyclonal rabbit anti-Yca1p antibody (kindly supplied by Dr. F. Madeo).

### 2.10. Statistical analysis

The arithmetic means for the free intracellular ROS and TUNEL staining quantification and comparison of cell survival rates are presented with standard deviation with a 95% confidence value. Statistical analysis was carried out using independent samples *t*-test analysis. A *p*-value lower than 0.05 was assumed to denote a significant difference.

## 3. Results

### 3.1. Digestome analysis reveals GAPDH as a cleavage target of metacaspase

To identify specific targets of yeast metacaspase we performed a digestome analysis, as previously described [14]. Although digestome analysis, an *in vitro* assay, does not mimic cellular physiological conditions, it represents a starting point for searching putative specific substrates of proteases. In a first dimension SDS-PAGE, total protein extracts from untreated wild-type yeast cells were resolved. Upon protein separation, gel lanes were excised and incubated with active metacaspase-enriched extracts obtained from YCA1<sup>overexp</sup> cells undergoing apoptosis induced by H<sub>2</sub>O<sub>2</sub> treatment (a condition known to induce metacaspase activation [3]). After incubation, gel lanes were mounted on a second SDS-PAGE gel and proteins resolved a second time by molecular weight. Digestome analysis of total protein extracts revealed numerous spots below the diagonal, corresponding to protein fragments that originated from cleavage during the incubation of the gel lane with active metacaspase-enriched extracts (Fig. 1A). Three spots (Fig. 1A, spot 1, 2 and 3) were analyzed by mass spectrometry and indicate the presence of peptide fragments of the isoforms 2 or 3 (Tdh2p/Tdh3p), but not of the isoform 1 (Tdh1p), of the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Fig. 1B). Immunoblotting of the digestome analysis gel with an anti-GAPDH antibody showed three GAPDH fragments immediately below the diagonal (Fig. 1C1, spots 4, 5 and 6). Some of these labeled fragments are most likely the complementary GAPDH protein fragments of the peptides identified by mass spectrometry (Fig. 1A and B).

The question whether GAPDH cleavage observed was due to metacaspase or to other activated proteases was addressed. For such purpose, gel lanes were also incubated either with extracts from untreated YCA1<sup>overexp</sup> cells or H<sub>2</sub>O<sub>2</sub>-treated  $\Delta$ ycal cells, two paradigmatic conditions of absence of metacaspase activity. Digestome analysis showed that the absence of metacaspase activity (Fig. 1C2 and C3) resulted in the appearance of a GAPDH fragment (spot 6) below the full-length GAPDH protein that is also present in the digestome obtained with H<sub>2</sub>O<sub>2</sub>-treated YCA1<sup>overexp</sup> cells, indicating that this is a biological phenomenon independent of metacaspase activity. However, two other spots (spots 4 and 5) were detected in the digestome analysis under active metacaspase conditions (Fig. 1C) and were not generated when active metacaspase was absent. These data suggest that GAPDH is cleaved by metacaspase and that specific cleavage products only occur when metacaspase is active.

The observed *in vitro* cleavage of GAPDH by active metacaspase-enriched extracts suggests a relevant role of metacaspase proteolytic activity in targeting a crucial metabolic enzyme during yeast apoptosis. In mammals, the targeting of metabolic enzymes by caspases is

not a newly described phenomenon as evidenced in the caspase substrate database (CASBAH database) [16].

### 3.2. Recombinant GAPDH is cleaved *in vitro* by recombinant metacaspase

To further support the specific cleavage of GAPDH by active metacaspase, recombinant metacaspase-enriched bacterial extracts were added to recombinant GAPDH (isoform 3 - Tdh3p, the main target of fragmentation during H<sub>2</sub>O<sub>2</sub>-induced apoptosis [9]). As shown in Fig. 2, the addition of a metacaspase-enriched bacterial extract to recombinant GAPDH was sufficient to induce its fragmentation, with the appearance of fragments with molecular weights similar to the ones detected in the immunoblot of the digestome gel (Fig. 1C1). When protein extracts from *E. coli* cells expressing the empty vector were added to GAPDH, no fragmentation was observed (Fig. 2). GAPDH has also been reported to be specifically cleaved by caspase-1 in higher eukaryotic cells [17]. Since GAPDH sequence is highly conserved among species, as a positive control, we added recombinant fish caspase-1 to recombinant yeast GAPDH. As expected, fish caspase-1 was able to cleave yeast GAPDH (Fig. 2), although the four resulting GAPDH fragments were distinct from the ones produced by incubation with recombinant yeast metacaspase, showing that these proteases have distinct cleavage target sites. Our results indicate that yeast metacaspase recognizes target sequences distinct from the ones recognized by caspases of higher eukaryotes corroborating previous results that attributed to metacaspase an arginine/lysine-specific endopeptidase activity in contrast to the cysteine-aspartic proteases of caspases [15].

Altogether, these results show that although metacaspases have a proteolytic activity distinct from caspases, their targeted molecular pathways upon an apoptotic stimulus display similarities and during apoptotic cell death both of them degrade metabolic enzymes. Next, we went on to evaluate if cleavage of GAPDH by metacaspase also occurs during *in vivo* induction of yeast apoptosis by H<sub>2</sub>O<sub>2</sub> [3].

### 3.3. *In vivo* metacaspase cleavage of GAPDH during H<sub>2</sub>O<sub>2</sub>-induced apoptosis is dependent on NO levels

Several proteins shown to be specifically cleaved by *in vitro* methodologies, such as the digestome analysis, proved later not to be substrates of the caspases under *in vivo* apoptotic conditions. Thus, metacaspase specific GAPDH fragmentation was evaluated by immunoblot analysis of the GAPDH levels, in total protein extracts from wild-type and  $\Delta$ ycal cells challenged with H<sub>2</sub>O<sub>2</sub>. As expected, H<sub>2</sub>O<sub>2</sub> (concentrations ranging from 0.5 mM to 2 mM) induced apoptotic cell death of wild-type cells as revealed by the increasing percentage of cells displaying TUNEL positive phenotype and high levels of reactive oxygen species (ROS) (Fig. 3). In contrast,  $\Delta$ ycal cells were more resistant to H<sub>2</sub>O<sub>2</sub> and thus have increased survival, TUNEL negative phenotype and lower percentage of cells with high ROS levels (Fig. 3). Moreover, apoptotic cell death of wild-type cells was accompanied by a clear reduction of the GAPDH levels that was not observed in  $\Delta$ ycal cells (Fig. 3E), suggesting the requirement of metacaspase for the occurrence of fragmentation of this protein *in vivo*. Simultaneously, it was possible to detect a GAPDH fragment with lower molecular weight (15 kDa) (Fig. 3E) compatible with one of the fragments observed by digestome analysis (Fig. 1C1). The absence of other fragments in the immunoblot analysis, as observed by *in vitro* digestome assay, suggests that the peptides liberated from the precursor protein, can be further processed, resulting in fragments that are released or degraded.

These results suggest that GAPDH is a specific target of metacaspase during H<sub>2</sub>O<sub>2</sub>-induced apoptosis, reinforcing the link between metabolism and cell death.

Our previous data have demonstrated that upon H<sub>2</sub>O<sub>2</sub>-induced apoptosis, yeast cells are able to synthesize nitric oxide (NO) leading to

**Fig. 1.** GAPDH is a target of cleavage by metacaspase-enriched protein extracts. (A) Total protein extracts from untreated wild-type cells subjected to SDS-PAGE, incubated with active metacaspase-enriched extracts (from  $H_2O_2$ -treated YCA1<sup>overexp</sup> cells) and then subjected to a second SDS-PAGE. The gel was Coomassie blue-stained. Spots below diagonal (1, 2 and 3), corresponding to cleaved proteins, were excised and analyzed by MALDI-TOF mass spectrometry. (B) Sequence of GAPDH isoforms Tdh1p (NP\_012483.1), Tdh2p (NP\_012542) and Tdh3p (NP\_011708) retrieved from NCBI. Mass spectrometry analyses of the three spots identified peptides matches to Tdh2p and Tdh3p but not Tdh1p. Sequence parts covered by the detected peptides are indicated with different colors. Pink colored peptide was identified both in spot 2 and 3. (C) Coomassie-stained diagonal gels of protein extracts from wild-type untreated cells incubated with protein extracts from (1)  $H_2O_2$ -treated YCA1<sup>overexp</sup> cells; (2) untreated YCA1<sup>overexp</sup> cells and (3)  $H_2O_2$ -treated  $\Delta yca1$  cells, and respective immunoblot analysis with a monoclonal anti-GAPDH antibody reveal spots 4, 5 and 6. Data are representative of at least three independent experiments.

the S-nitrosation of GAPDH [9]. Therefore, we wondered if the metacaspase specific GAPDH cleavage and NO signaling are correlated. To elucidate if GAPDH metacaspase-dependent fragmentation requires its previous S-nitrosation, NO synthesis was inhibited, through the pre-incubation of cells with the L-arginine analog  $N_\omega$ -nitro-L-arginine methyl ester (L-NAME) [9,10], and the in vivo GAPDH levels assessed

by immunoblot. NO synthesis inhibition resulted in the maintenance of GAPDH levels, in contrast with the  $H_2O_2$ -treated wild-type cells without L-NAME pre-incubation (Fig. 3F). These results revealed a causal relation between metacaspase activity and NO levels, as previously reported [7,10] indicating that the in vivo occurrence of metacaspase specific GAPDH cleavage upon  $H_2O_2$ -induced apoptosis requires NO signaling.

#### 4. Discussion

Metacaspase seems to be an executor of the apoptotic events observed in *S. cerevisiae* (reviewed in [4,12]). Although significant efforts have gone into the clarification of the role of metacaspase in yeast cell death processes, its role is still enigmatic. The routes to unravel yeast metacaspase functions undoubtedly have to pass through understanding how metacaspase recognizes its substrates, the identification of its specific substrates and how substrate cleavage is involved in the apoptotic phenotype. Although it was described that in vivo metacaspases cleave the evolutionarily conserved TSN (Tudor staphylococcal nuclease) [11], TSN is absent in budding yeast [11] and thus the substrates targeted by yeast metacaspase are still unknown.

**Fig. 2.** In vitro cleavage of recombinant GAPDH by metacaspase-enriched bacterial extracts and purified caspase-1. Immunoblot of recombinant GAPDH incubated with 20  $\mu$ l of protein extracts from bacteria harboring pET23a empty vector, 20  $\mu$ l of protein extracts from bacteria expressing metacaspase or recombinant purified caspase-1. Twenty microliters of protein extracts from bacterial cells expressing metacaspase were loaded as control. Data are representative of at least three independent experiments.

**Fig. 3.** GAPDH specific cleavage by metacaspase during H<sub>2</sub>O<sub>2</sub>-induced apoptosis is dependent on NO levels. (A) Comparison of the survival rate of wild-type and  $\Delta yca1$  cells upon H<sub>2</sub>O<sub>2</sub> treatment. (B) Percentage of wild-type and  $\Delta yca1$  cells exhibiting high levels of intracellular ROS detected by FACS measurements of the dihydrorhodamine 123 fluorescence. (C) Percentage of wild-type and  $\Delta yca1$  cells displaying TUNEL positive phenotype. (D) Epifluorescence and bright field micrographs of untreated and H<sub>2</sub>O<sub>2</sub>-treated wild-type and  $\Delta yca1$  cells displaying TUNEL reaction to visualize double-strand DNA breaks. Cells were co-stained with propidium iodide in order to facilitate nuclei visualization. Bar, 5  $\mu$ m. (E) Immunoblot analysis of GAPDH and actin protein levels in 40  $\mu$ g of total protein extracts of H<sub>2</sub>O<sub>2</sub>-treated and untreated wild-type and  $\Delta yca1$  cells. (F) Immunoblot analysis of GAPDH levels in 40  $\mu$ g of total protein extracts of untreated and H<sub>2</sub>O<sub>2</sub>-treated wild-type yeast cells after pre-incubation with the L-arginine analog, L-NAME. Statistical significance (\* $P < 0.05$ ) was determined by Student's *t*-test.

The use of different methodologies described as requisites for a protein to be considered a caspase substrate [18] allows us to assign GAPDH as a metacaspase specific substrate. GAPDH cleavage was observed in vitro by digestome analysis complemented with mass spectrometry and immunoblot and validated by its specific cleavage after incubation of recombinant GAPDH with recombinant metacaspase. Moreover, the occurrence of GAPDH metacaspase-dependent cleavage was further confirmed by an in vivo assay in cells undergoing apoptosis with GAPDH displaying reduced levels. Moreover, the physiological relevance of GAPDH fragmentation is also supported by previous results showing that GAPDH is a target of extensive fragmentation upon H<sub>2</sub>O<sub>2</sub>-induced apoptosis [9,19]. It is important to acknowledge that, proteolytic cleavage of GAPDH, as that of any protein, can result in a gain- or loss-of-function for the protein. It is well known that H<sub>2</sub>O<sub>2</sub> treatment (1.5 mM) of *S. cerevisiae* cells results in the decrease of GAPDH activity associated with a drop of the ATP levels [20]. The reduced ATP levels affect cellular homeostasis and can decrease the efficiency of energy-dependent processes and ATP-mediated cell signal transduction such as actin dynamics [21] increasing the sensitivity to apoptotic insult. Nevertheless, the hypothesis that GAPDH cleavage results in a gain-of-function is also acceptable in the light of our previous results [9] showing an increased survival of *TDH2*- and *TDH3*-disrupted cells exposed to H<sub>2</sub>O<sub>2</sub>-induced apoptosis. The GAPDH pleiotropic

functions, linked to the various intracellular localizations of the enzyme, as well as the observation that GAPDH overexpressing cells behave as wild-type cells when challenged with H<sub>2</sub>O<sub>2</sub> (data not shown) further complicates the elucidation of this aspect. Nonetheless, the accumulating evidence indicates that yeast GAPDH cleavage by metacaspase could contribute to H<sub>2</sub>O<sub>2</sub>-induced apoptosis independently of whether or not this proteolysis results in a gain- or loss-of-function. We and others have shown that GAPDH is S-nitrosated by the NO generated upon H<sub>2</sub>O<sub>2</sub>-induced apoptosis [9], and that inhibition of NO synthesis in yeast cell leads to a dramatic reduction of metacaspase activity [10]. Herein we show that NO production is needed for the metacaspase specific cleavage of GAPDH upon H<sub>2</sub>O<sub>2</sub>-induced apoptosis, similar to what occurs in higher eukaryotic cells, in which NO has already been ascertained as a signaling molecule with the capacity to promote caspase activation [22]. The observed NO-dependent metacaspase specific cleavage of GAPDH might also be explained by the capacity of NO in activating metacaspase as previously reported [7]. Further studies might help in elucidating the relation between NO signaling and metacaspase specific GAPDH cleavage. Nonetheless, all these results call attention to the relevance of metabolic enzyme cleavage during H<sub>2</sub>O<sub>2</sub>-induced apoptosis. Metabolic enzymes have complex roles, having proved their multi-functional relation with different cellular processes, including cell death [23,24]. In fact, GAPDH has been extensively implicated in

several mammalian apoptotic processes [25]. Additionally, alterations in metabolic pathways are often related to neurodegenerative diseases, cell damaging processes and cancers [23,25]. Our findings herein described demonstrate for the first time a yeast metacaspase specific substrate, GAPDH. The data obtained open new perspectives for the precise identification of the molecular cascade regulated by metacaspase activation and its relevance to yeast apoptotic cell death.

**Table 5** - Microarrays analysis results of polysomal fractions of 15 and 30 min acetic acid treated cells. 42 genes were found up-regulated (more than two fold) upon acetic acid treatment.
